Let us now return to the remaining properties of FFHs listed above under (ii) to (v). (ii) What does it mean for a heuristic to have evolved as a fundamental psychological mechanism? First, recall our discussion of the second and third reading of the term heuristics: the functioning of the psychological mechanism is directly represented as the heuristic procedure, not as an abstraction from a more complex ideal procedure that has occurred to cognitively function in spite of limited cognitive resources. One may similarly argue that such resource limitations are equally products of adaptation to environmental structures, as we have done above. Second, the individual judgment and decision making strategies may be direct consequences of natural selection; for instance, with regard to sexual selection or feeding behavior in animals [16]. (iii) Fast heuristics are those that allow for quick decisions and judgments; for example, they are easy to use. Frugal heuristics are those that (can) operate on only little of the available information and do not involve much and complex computation. This implies that not only are the processes that integrate information to make a decision frugal, but also that there exist rules that quickly stop search for and integration of information once a specific criterion has been reached [24]. (iv) What does it mean for heuristics to be precise enough to be amenable for computational modeling? Computational descriptions of behavior have been ascribed with a number of advantages over, for instance, conceptual descriptions in particular, because of the required levels of specificity [25]. FHH are precise and they can be sufficiently specified, for instance in terms of search rules, stop rules, and

decision rules that can (and have been) computationally modeled and tested. (v) Gigerenzer *et al.* [23] further suggest that general psychological plausibility is important for models of cognition in general and that the FFHs are, in fact, psychologically plausible. They break plausibility down to tractability in realistic scenarios rather than in artificial test boxes, to robustness (i.e., low model complexity, few or no free parameters), to frugality and speed in reaching decisions, and to evidence (i.e., the model should be consistent with other accepted findings and computational explanations of cognition).

EMPIRICAL EVALUATION AND MODELING

As laid down in Refs 5 and 1, the FFH research program is meant to include a systematic evaluation of the proposed heuristics. Such evaluation should be carried out with respect to three minimum criteria: (i) multiple models need to be tested against each other to determine relative predictiveness; (ii) models need to be tested for individuals as individuals differ in the strategies that they use; and (iii) a test of adaptive selection—test whether individuals employ heuristics where their use is ecologically rational. Also, with respect to the desired degree of psychological plausibility, models need to be tested in larger computational contexts, such as in the frameworks of the commonly used cognitive architectures and memory models (see Ref. 24, for a discussion on past and ongoing activities related to the ACT-R cognitive architecture). These approaches can again inform research on which heuristics humans and animals use, and on which heuristics they use given certain structures of information in the environment. Without the proper analysis of a heuristic's use in practice, it is little more than an interesting theoretical account of a procedural mechanism. With a proper analysis, it may in fact add much to our knowledge about cognitive procedures in judgment and decision making, as well as inform the design of environmental conditions and applications that improve human judgment and decision making.

TAKE-HOME MESSAGE FOR THE DECISION SCIENTIST

The FFH research effort offers an intriguing perspective on heuristics that constitute a set of fundamental psychological mechanisms through which humans make judgments, reach decisions, and act upon the environment. In this view, heuristics are no second-class procedures that are carried out only because one cannot computationally or cognitively “afford” to execute better procedures (e.g., due to cognitive limitations), but rather, heuristics constitute an effective and highly efficient group of procedures in their own right. Some FFHs exhibit so-called less-is-more effects by which accuracy of predictions is actually increased under less information. These effects are contrary to outcomes expected under traditional beliefs in general accuracy–effort trade-offs and they are further indications of the power of simple heuristics in judgment and decision making.

ALGORITHM DESCRIPTION

The feasible direction method is an important class of algorithms for solving constrained nonlinear optimization problems. Each iteration of a feasible direction method consists of two steps:

- Step 1.* Compute a feasible direction (i.e., a direction along which there exists a piece of segment lying inside of feasible region.)
- Step 2.* Carry out a line-search along the feasible direction obtained in Step 1, to obtain a new feasible point.

There are many ways to compute a feasible direction and also many ways to do line-search. Computing a feasible direction and doing line-search are usually independent. Each method for computing a feasible direction can be combined with any line-search procedure to form a feasible direction method. However, the classification of feasible direction methods are mainly based on the way for computing a feasible direction. In the literature, there are three classical methods,

Zoutendijk's Method [1], Wolfe's method [2,3], and Rosen's method [4,5]. In this article, we survey various historical issues about them, including their global convergence and extension to nonlinear constrained optimization.

Zoutendijk's Method, Wolfe's method, and Rosen's method are initially proposed for solving linearly constrained nonlinear optimization problems.

Zoutendijk's Method

Consider the following problem:

$$\begin{aligned} & \text{maximize } f(\mathbf{x}) \\ & \text{subject to } h_j(\mathbf{x}) \geq 0, j = 1, 2, \dots, m, \end{aligned}$$

where f and h_j are continuously differentiable functions on R^n . Zoutendijk [1] gave the following algorithm.

Initially, choose a starting feasible point $\mathbf{x}_1$. At each iteration $k = 1, 2, \dots$, solve the following linear programming

$$\begin{aligned} & \text{maximize } z \\ & \text{subject to } \nabla f(\mathbf{x}_k)^T \mathbf{d} - z \geq 0, \\ & \quad \nabla h_j(\mathbf{x}_k)^T \mathbf{d} - z \geq 0 \quad \text{for } j \in J_k, \\ & \quad -1 \leq d_i \leq 1 \quad \text{for } i = 1, \dots, n, \end{aligned} \tag{1}$$

where d_i is the i th component of $\mathbf{d}$. Let $(z_k, \mathbf{d}_k)$ be an optimal solution of the linear programming. If $z_k = 0$, then stop; $\mathbf{x}_k$ is a Fritz John point. If $z_k > 0$, then choose an appropriate $\bar{\lambda}_k$ such that for $\lambda \in [0, \bar{\lambda}_k]$, $\mathbf{x}_k + \lambda \mathbf{d}_k$ is feasible, and find a new feasible point $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda_k \mathbf{d}_k$ ($0 < \lambda_k \leq \bar{\lambda}_k$) by a line-search procedure.

Wolfe's Reduced Gradient Method

Consider the following problem:

$$\begin{aligned} & \text{maximize } f(\mathbf{x}) \\ & \text{subject to } \mathbf{Ax} = \mathbf{b} \\ & \quad \mathbf{x} \geq \mathbf{0}, \end{aligned}$$

where $\mathbf{A}$ is an $m \times n$ matrix of rank m , and $\mathbf{b}$ is an m -dimensional vector. Assume that every basic feasible solution is nondegenerate. Wolfe [3] suggested the following algorithm.

Choose an initial point $\mathbf{x}_1$. At iteration $k = 1, 2, \dots$ with point $\mathbf{x}_k$, the following steps are carried out.

1. Find a feasible basis I_k such that $x_{ki} > 0$ for all $i \in I_k$, where x_{ki} is the i component of $\mathbf{x}_k$. Divide n variables into two groups $\mathbf{x}_k, I_k = (x_{ki}, i \in I_k)$ and $\mathbf{x}_k, \bar{I}_k = (x_{ki}, i \in \bar{I}_k)$, where $\bar{I}_k = \{1, \dots, n\} \setminus I_k$. Computer

$$\mathbf{r} = \nabla f(\mathbf{x}_k) - (\mathbf{A}_{I_k}^{-1} \mathbf{A})^T \nabla_{I_k} f(\mathbf{x}_k),$$

where $\nabla_{I_k} f(\mathbf{x}_k)$ is a subvector of $\nabla f(\mathbf{x}_k)$ with indices in I_k and $\mathbf{A}_{I_k}$ is a submatrix of $\mathbf{A}$ with column indices in I_k . Choose the search direction $\mathbf{d}_k = (d_{k1}, \dots, d_{kn})^T$ by first setting that for $i \in \bar{I}_k$,

$$d_{ki} = \begin{cases} 0 & \text{if } r_{ki} \leq 0 \text{ and } x_{ki} = 0, \\ r_{ki} & \text{otherwise.} \end{cases}$$

and then setting

$$\mathbf{d}_k = \begin{pmatrix} -\mathbf{A}_I^{-1} \mathbf{A}_{\bar{I}_k} \mathbf{d}_{k, \bar{I}_k} \\ \mathbf{d}_{k, \bar{I}_k} \end{pmatrix}.$$

If $\mathbf{d}_k = \mathbf{0}$, then stop ($\mathbf{x}_k$ is a Kuhn-Tucker point). Otherwise go to the next step.

2. Define

$$\bar{\lambda}_k = \begin{cases} 1 & \text{if } d_{ki} \geq 0 \text{ for all } i, \\ \min \left\{ \frac{x_{ki}}{-d_{ki}} \mid d_{ki} < 0 \right\} & \text{otherwise.} \end{cases}$$

Find a new point $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda_k \mathbf{d}_k$ by a line-search procedure.

Rosen's Gradient Projection Method

Consider the following problem:

$$\begin{aligned} & \text{maximize} && f(\mathbf{x}) \\ & \text{subject to} && \mathbf{a}^T \mathbf{x} = b_j, \quad j = 1, 2, \dots, m', \\ & && \mathbf{a}^T \mathbf{x} \geq b_j, \quad j = m' + 1, \dots, m. \end{aligned} \quad (2)$$

Denote $M = \{1, 2, \dots, m\}$ and $M' = \{1, 2, \dots, m'\}$. For any $J \subseteq M$, denote $D_J = \{\mathbf{d} \mid \mathbf{a}^T \mathbf{d} = 0, j \in J\}$. P_J is the orthogonal projection operator for subspace D_J . Let $J(\mathbf{x})$ denote the active index set at $\mathbf{x}$. In particular, we denote $J_k = J(\mathbf{x}_k)$ and $J^* = J(\mathbf{x}^*)$. Throughout this article, we assume that for every feasible point $\mathbf{x}$, $\mathbf{a}_j, j \in J(\mathbf{x})$ are linearly independent.

Rosen's method is as follows:

Initially, choose a feasible point $\mathbf{x}_1$. At each iteration $k = 1, 2, \dots$, the algorithm carries out the following steps:

1. Choose a positive number c_k . Compute a search direction by the following formula.

$$\mathbf{d}_k = \begin{cases} P_{J_k} \mathbf{g}_k & \text{if } \|P_{J_k} \mathbf{g}_k\| > c_k u_{kh_k}, \\ P_{J_k \setminus h_k} \mathbf{g}_k & \text{otherwise,} \end{cases}$$

where

$$(u_{kj}, j \in J_k)^T = (\mathbf{A}_{J_k}^T \mathbf{A}_{J_k})^{-1} \mathbf{A}_{J_k}^T \mathbf{g}_k$$

and

$$u_{kh_k} = \max\{u_{kj} \mid j \in J \setminus M'\}.$$

2. If $\mathbf{d}_k = \mathbf{0}$, then stop; $\mathbf{x}_k$ is a Kuhn-Tucker point. If $\mathbf{d}_k \neq \mathbf{0}$, then compute

$$\bar{\lambda}_k = \begin{cases} 1 & \text{if } \mathbf{a}_j^T (\mathbf{x}_k + \mathbf{d}_k) \geq b_j \text{ for all } j \notin J_k, \\ \min \left\{ \frac{b_j - \mathbf{a}_j^T \mathbf{x}_k}{\mathbf{a}_j^T \mathbf{d}_k} \mid \mathbf{a}_j^T (\mathbf{x}_k + \mathbf{d}_k) < b_j \right\} & \text{otherwise,} \end{cases}$$

and find a new point $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda_k \mathbf{d}_k$ ($0 < \lambda_k \leq \bar{\lambda}_k$) by a line-search procedure.

There are many choices for the line-search procedure. The following are some examples.

Accurate Line-Search 1. The procedure computes a solution λ^+ for the problem of maximizing $f(\mathbf{x} + \lambda \mathbf{d})$ subject to $0 \leq \lambda \leq \bar{\lambda}$, and set $\mathbf{x}^+ = \mathbf{x} + \lambda^+ \mathbf{d}$.

Accurate Line-Search 2. The procedure finds the first local maximum λ^+ for the function $f(\mathbf{x} + \lambda \mathbf{d})$ with respect to λ over $[0, \bar{\lambda}]$, and set $\mathbf{x}^+ = \mathbf{x} + \lambda^+ \mathbf{d}$.

Goldstein Test. Select a constant α from $(0, 1/2)$. The procedure computes a new feasible point $\mathbf{x}^+ = \mathbf{x} + \lambda^+ \mathbf{d}$ ($0 < \lambda^+ \leq \bar{\lambda}$) such that

$$\alpha \lambda^+ \mathbf{g}(\mathbf{x})^T \mathbf{d} \leq f(\mathbf{x}^+) - f(\mathbf{x})$$

and either $\lambda^+ = \bar{\lambda}$ or

$$(1 - \alpha) \lambda^+ \mathbf{g}(\mathbf{x})^T \mathbf{d} \geq f(\mathbf{x}^+) - f(\mathbf{x}).$$

Wolfe Test. Select a constant α from $(0, 1/2)$. The procedure computes a feasible point $\mathbf{x}^+ = \mathbf{x} + \lambda^+ \mathbf{d}$ ($0 < \lambda^+ \leq \bar{\lambda}$) such that

$$\alpha \lambda^+ \mathbf{g}(\mathbf{x})^T \mathbf{d} \leq f(\mathbf{x}^+) - f(\mathbf{x})$$

and either $\lambda^+ = \bar{\lambda}$ or

$$(1 - \alpha) \mathbf{g}(\mathbf{x})^T \mathbf{d} \geq \mathbf{g}(\mathbf{x}^+)^T \mathbf{d}.$$

Armijo's Rule. The procedure finds a point $\mathbf{x}^+ = \mathbf{x} + \lambda^+ \mathbf{d}$ ($0 < \lambda^+ \leq \bar{\lambda}$) such that

$$\frac{1}{2} \lambda^+ \mathbf{g}(\mathbf{x})^T \mathbf{d} \leq f(\mathbf{x}^+) - f(\mathbf{x})$$

and either $\lambda^+ = \bar{\lambda}$ or

$$\lambda^+ \mathbf{g}(\mathbf{x})^T \mathbf{d} > f(\mathbf{x} + 2\lambda^+ \mathbf{d}) - f(\mathbf{x}).$$

Each line-search procedure can be considered as a point-to-set mapping from the point $(\mathbf{x}, \mathbf{d}, \bar{\lambda})$ to the set of all possible $\mathbf{x}^+$'s. Usually, a line-search procedure T have the following properties:

1. $\forall \mathbf{x}^+ \in T(\mathbf{x}, \mathbf{d}, \bar{\lambda}) : f(\mathbf{x}^+) > f(\mathbf{x})$.
2. If $\mathbf{g}(\mathbf{x})^T \mathbf{d} > 0$ and $0 < \bar{\lambda} < \infty$, then $T(\mathbf{x}, \mathbf{d}, \bar{\lambda}) \neq \emptyset$.

We call a line-search procedure T *normal* if in addition, it satisfies

$$\left. \begin{array}{l} \mathbf{x}_k \rightarrow \mathbf{x}^* \\ \mathbf{d}_k \rightarrow \mathbf{d}^* \\ \mathbf{x}_k^+ \in T(\mathbf{x}_k, \mathbf{d}_k, \bar{\lambda}_k) \\ f(\mathbf{x}_k^+) \rightarrow f(\mathbf{x}^*) \end{array} \right\} \Rightarrow \text{either } \lambda_k^+ \rightarrow 0 \text{ or } (\mathbf{g}^*)^T \mathbf{d}^* \leq 0 \quad (3)$$

and

$$\left. \begin{array}{l} \mathbf{x}_k \rightarrow \mathbf{x}^* \\ \mathbf{d}_k \rightarrow \mathbf{d}^* \\ \mathbf{x}_k^+ \in T(\mathbf{x}_k, \mathbf{d}_k, \bar{\lambda}_k) \\ f(\mathbf{x}_k^+) \rightarrow f(\mathbf{x}^*) \end{array} \right\} \Rightarrow \begin{array}{l} \text{either } (\mathbf{g}^*)^T \mathbf{d}^* \leq 0 \\ \text{or } \exists k_0 \forall k \geq k_0 : \lambda_k^+ = \bar{\lambda}_k \end{array}, \quad (4)$$

where $\mathbf{x}_k^+ = \mathbf{x}_k + \lambda_k^+ \mathbf{d}_k$.

In order for a feasible direction method to have a good performance, we usually choose to use a normal line-search procedure. All the above five line-search procedures (Accurate Line-Search 1 and 2, Armijo's Rule, Goldstein Test, and Wolfe Test) have been proved to be normal [6].

GLOBAL CONVERGENCE

Wolfe [3] gave a counterexample to show that Zoutendijk's method may generate a sequence of points converging to a point which is not a Fritz John point. There is a counterexample [2,7] to show that Wolfe's method may also generate a sequence convergent to a point which is not a Kuhn–Tucker point. The global convergence of Rosen's method was a well-known long-standing open problem, and its proof was found by Bazaraa and Shetty [7] and Du and Zhang [8,9].

Although Zoutendijk's method and Wolfe's method may generate a convergent sequence of points not convergent to a stationary point, such as a Fritz John point or a Kuhn–Tucker point, they still hold certain global convergence that if generated sequence is not convergent then every cluster point is a Fritz John point or a Kuhn–Tucker point. This is

due to a very powerful tool, slope lemma [6] given as follows:

Lemma 1 [Slope Lemma]. *Let $\{\mathbf{x}_k\}$ be a sequence of feasible points satisfying that $f(\mathbf{x}_k) < f(\mathbf{x}_{k+1})$ for $k = 1, 2, \dots$. Let $\mathbf{x}^*$ be a cluster point of the sequence satisfying that*

() for any subsequence $\{\mathbf{x}_k\}_{k \in K}$ convergent to $\mathbf{x}^*$, $\mathbf{x}_{k+1} - \mathbf{x}_k \rightarrow \mathbf{0}$ as $k \rightarrow \infty, k \in K$.*

If $\{\mathbf{x}_k\}$ is not convergent to $\mathbf{x}^$, then there exists a subsequence $\{\mathbf{x}_k\}_{k \in K}$ such that*

- (a) $\mathbf{x}_k \rightarrow \mathbf{x}^*$ as $k \rightarrow \infty, k \in K$, and
- (b) $\lim_{k \rightarrow \infty, k \in K} \frac{\nabla f(\mathbf{x}_k)^T (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} = 0$.

Proof. Note that for any subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$, we have

$$\begin{aligned} \lim_{k \rightarrow \infty, k \in K} \frac{\nabla f(\mathbf{x}_k)^T (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} \\ = \lim_{k \rightarrow \infty, k \in K} \frac{f(\mathbf{x}_{k+1}) - f(\mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|}, \end{aligned}$$

since

$$\begin{aligned} & \left| \frac{\nabla f(\mathbf{x}_k)^T (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} - \frac{f(\mathbf{x}_{k+1}) - f(\mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} \right| \\ &= \left| \frac{(\nabla f(\mathbf{x}_k) - \nabla f(\mathbf{y}_k))^T (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} \right| \\ &\leq \|\nabla f(\mathbf{x}_k) - \nabla f(\mathbf{y}_k)\|, \end{aligned}$$

where $\mathbf{y}_k$ is a point on the segment $[\mathbf{x}_k, \mathbf{x}_{k+1}]$. Suppose that the lemma is false. Then for any subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$,

$$\liminf_{k \rightarrow \infty, k \in K} \frac{f(\mathbf{x}_{k+1}) - f(\mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} > 0.$$

By a diagonalization argument, we can see that there exists a positive number ε such that for every subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$,

$$\liminf_{k \rightarrow \infty, k \in K} \frac{f(\mathbf{x}_{k+1}) - f(\mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} \geq \varepsilon. \quad (5)$$

It follows that there exists a positive number δ such that for all k , $\|\mathbf{x}_k - \mathbf{x}^*\| \leq \delta$ implies

$$f(\mathbf{x}_{k+1}) - f(\mathbf{x}_k) \geq \frac{\varepsilon}{2} \|\mathbf{x}_{k+1} - \mathbf{x}_k\|. \quad (6)$$

In fact, if such a positive number δ does not exist, then we can find a subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$ and satisfying that for $k \in K$,

$$\frac{f(\mathbf{x}_{k+1}) - f(\mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} < \varepsilon/2,$$

contradicting Equation (6).

Since $\{\mathbf{x}_k\}$ does not converge to $\mathbf{x}^*$, there exists a positive number $\delta' < \delta$ such that $\|\mathbf{x}_k - \mathbf{x}^*\| > \delta'$ for infinitely many k . Define $B(\delta') = \{\mathbf{x} \mid \|\mathbf{x} - \mathbf{x}^*\| \leq \delta'\}$. For each $\mathbf{x}_k \in B(\delta')$, denote by k' the smallest $k' \geq k$ such that $\mathbf{x}_{k'} \notin B(\delta')$. Choose an infinite sequence $\{k_i\}$ such that $\mathbf{x}_{k_i} \in B(\delta'/2)$ and $k_i < k'_i < k_{i+1} < k'_{i+1}$ for every i . Now, we have

$$\begin{aligned} f(\mathbf{x}^*) - f(\mathbf{x}_{k_1}) &\geq \sum_{i=1}^{\infty} \sum_{j=k_i}^{k'_i-1} (f(\mathbf{x}_{j+1}) - f(\mathbf{x}_j)) \\ &\geq \sum_{i=1}^{\infty} \sum_{j=k_i}^{k'_i-1} \frac{\varepsilon}{2} \|\mathbf{x}_{j+1} - \mathbf{x}_j\| \\ &\geq \sum_{i=1}^{\infty} \frac{\varepsilon}{2} \|\mathbf{x}_{k'_i} - \mathbf{x}_{k_i}\| \\ &\geq \sum_{i=1}^{\infty} \frac{\varepsilon}{2} \cdot \frac{\delta'}{2} = \infty, \end{aligned} \quad (7)$$

by Equation (7), a contradiction.

The following is a corollary of the above slope lemma.

Corollary 1. *Let $\{\mathbf{x}_k\}$ be a sequence of feasible points generated by an algorithm described as above. Suppose that $f(\mathbf{x}_{k+1}) > f(\mathbf{x}_k)$ for all k . Consider a cluster point $\mathbf{x}^*$ of sequence $\{\mathbf{x}_k\}$ satisfying that*

- (a) *for every subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$, $\{\mathbf{d}_k\}_{k \in K}$ is bounded, and*
- (b)

$$\left. \begin{aligned} \lim_{k \rightarrow \infty, k \in K} \mathbf{x}_k &= \mathbf{x}^* \\ \lim_{k \rightarrow \infty, k \in K} \mathbf{d}_k &= \mathbf{d}^* \\ \nabla f(\mathbf{x}^*)^T \mathbf{d}^* &> 0 \end{aligned} \right\}$$

$$\implies \mathbf{x}_{k+1} - \mathbf{x}_k \rightarrow \mathbf{0} \text{ as } k \rightarrow \infty, k \in K.$$

If $\{\mathbf{x}_k\}$ does not converge to $\mathbf{x}^$, then there exists a subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$ such that $\lim_{k \rightarrow \infty, k \in K} \mathbf{d}_k = \mathbf{d}^*$ and $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* = 0$.*

Proof. Consider two cases.

Case 1. There is a subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$ such that $\|\mathbf{x}_{k+1} - \mathbf{x}_k\| > \varepsilon$ for all $k \in K$ and a positive number ε . Since $\{\mathbf{d}_k\}_{k \in K}$ is bounded, there is a subsequence $\{\mathbf{x}_k\}_{k \in K'}$ ($K' \subset K$) such that $\{\mathbf{d}_k\}_{k \in K'}$ converges to a vector $\mathbf{d}^*$. Since $\mathbf{d}_k$ is an ascending direction at $\mathbf{x}_k$, we have $\nabla f(\mathbf{x}_k)^T \mathbf{d}_k > 0$ for every k . Thus, $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* \geq 0$. By (d), we can conclude that $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* = 0$.

Case 2. For every subsequence $\{\mathbf{x}_k\}_{k \in K}$ converging to $\mathbf{x}^*$, $\mathbf{x}_{k+1} - \mathbf{x}_k \rightarrow \mathbf{0}$ as $k \rightarrow \infty, k \in K$. By the first slope lemma, there exists a subsequence $\{\mathbf{x}_k\}_{k \in K}$ such that

$$\lim_{k \rightarrow \infty, k \in K} \frac{\nabla f(\mathbf{x}_k)^T (\mathbf{x}_{k+1} - \mathbf{x}_k)}{\|\mathbf{x}_{k+1} - \mathbf{x}_k\|} = 0.$$

Let $\mathbf{d}^*$ be a cluster point of $\{\mathbf{d}_k\}_{k \in K}$. Then

$$\frac{\nabla f(\mathbf{x}^*)^T \mathbf{d}^*}{\|\mathbf{d}^*\|} = \lim_{k \rightarrow \infty, k \in K} \frac{\nabla f(\mathbf{x}_k)^T \mathbf{d}_k}{\|\mathbf{d}_k\|} = 0.$$

Therefore, $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* = 0$.

In the above corollary, the condition (d) is important to the contradiction argument. In fact, we see that for some algorithms, $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* = 0$ implies that $\mathbf{x}^*$ is a Kuhn–Tucker point or a Fritz John point. So, $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* > 0$ is an assumption for contradiction. A more important fact is that condition (d) holds for every normal line-search.

Next, let us apply this corollary to Zoutendijk's method, Wolfe's method, and Rosen's method.

Theorem 1. *If an infinite sequence of points generated by Zoutendijk's method does not converge, then every cluster point of the sequence is a Fritz John point.*

If an infinite sequence of points generated by Wolfe's method does not converge, then every cluster point of the sequence is a Kuhn–Tucker point.

If an infinite sequence of points generated by Rosen's method does not converge, then every cluster point of the sequence is a Kuhn–Tucker point.

Proof. Proofs for three statements are similar. Thus, we give the proof only for the first statement as an example.

First, we claim that (d) holds because we use a normal line-search procedure. Secondly, we claim that

$$\left. \begin{aligned} \lim_{k \rightarrow \infty, k \in K} \mathbf{x}_k &= \mathbf{x}^* \\ \lim_{k \rightarrow \infty, k \in K} \mathbf{d}_k &= \mathbf{d}^* \\ \nabla f(\mathbf{x}^*)^T \mathbf{d}^* &= 0 \end{aligned} \right\} \Rightarrow \mathbf{x}^* \text{ is a Fritz John point.}$$

To show our claim, let $\mathbf{x}_k \rightarrow \mathbf{x}^*$ and $\mathbf{d}_k \rightarrow \mathbf{d}^*$ such that $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* = 0$, where $\mathbf{d}_k$ is determined at $\mathbf{x}_k$ by Zoutendijk's method, that is, there is a number z_k such that $(z_k, \mathbf{d}_k)$ is an optimal solution of the linear programming (Eq. 1). Denote $z^* = \limsup_{k \rightarrow \infty, k \in K} z_k$. Since $\nabla f(\mathbf{x}_k)^T \mathbf{d}_k - z_k \geq 0$, we have $-z^* \geq 0$. However, since $(z, \mathbf{d}) = (0, \mathbf{0})$ is always a feasible solution of Equation (1), we have $z_k \geq 0$ for all k . Thus, $z^* = 0$. Without loss of generality, we assume that for every k , $J_k = J$ for a certain index set J . (Otherwise, we can study a subsequence with the property.) Next, we show that z^* is the optimal value of the following problem:

$$\begin{aligned} &\text{maximize} && z \\ &\text{subject to} && \nabla f(\mathbf{x}^*)^T \mathbf{d} - z \geq 0, \\ & && \nabla h_j(\mathbf{x}^*)^T \mathbf{d} - z \geq 0 \text{ for } j \in J, \\ & && -1 \leq d_i \leq 1 \text{ for } i = 1, \dots, n. \end{aligned} \quad (8)$$

In fact, if z^* is not the optimal value, then there exists a feasible solution of Equation (8), $(z', \mathbf{d}')$ with $z' > 0$. It follows that for sufficiently large k , $(z'/2, \mathbf{d}')$ is a feasible solution of Equation (1). So, $z_k \geq z'/2$ for such k 's. Letting $k \rightarrow \infty$, we have $0 = z^* \geq z'/2$, a contradiction. Therefore, $z^* = 0$ is the optimal value of Equation (8). It implies that the following system of inequalities has no solution.

$$\begin{aligned} &z > 0, \\ &\nabla f(\mathbf{x}^*)^T \mathbf{d} - z \geq 0, \\ &\nabla h_j(\mathbf{x}^*)^T \mathbf{d} - z \geq 0, \text{ for } j \in J. \end{aligned}$$

(If the system has a solution $(z, \mathbf{d})$, we can obtain a feasible solution with $z > 0$ for

Equation (8) by normalizing $\mathbf{d}$.) Hence, there exist $u > 0$, $v > 0$, and $w_j \geq 0$ for $j \in J$ such that

$$\begin{aligned} v \nabla f(\mathbf{x}^*) + \sum_{j \in J} w_j \nabla h_j(\mathbf{x}^*) &= \mathbf{0}, \\ u - v - \sum_{j \in J} w_j &= 0. \end{aligned}$$

$u > 0$ implies $v + \sum_{j \in J} w_j \neq 0$. Therefore, $\mathbf{x}^*$ is a Fritz John point.

Clearly, the search direction determined by Zoutendijk's method is bounded by $\sqrt{n}$. Let $\{\mathbf{x}_k\}$ be an infinite sequence generated by Zoutendijk's method and $\mathbf{x}^*$ a cluster point of the sequence. Suppose that $\{\mathbf{x}_k\}$ does not converge to $\mathbf{x}^*$. By Corollary 1, there is a subsequence $\{\mathbf{x}_{k_i}\}_{i \in K}$ converging to $\mathbf{x}^*$ such that $\{\mathbf{d}_{k_i}\}_{i \in K}$ converges to $\mathbf{d}^*$ with $\nabla f(\mathbf{x}^*)^T \mathbf{d}^* = 0$.

By our claim, $\mathbf{x}^*$ is a Fritz John point.

While convergent sequence generated by Zoutendijk's method and Wolfe's method may not converge to a Fritz John point or a Kuhn–Tucker point, convergent sequence generated by Rosen's method is still convergent to a Kuhn–Tucker point.

Theorem 2. *Let α and β be two positive numbers with $\alpha < \beta$. Suppose that $\alpha \leq c_k \leq \beta$ for all k . Then Rosen's method with a normal line-search procedure either stops at a Kuhn–Tucker point or generates an infinite sequence whose cluster points are all Kuhn–Tucker points.*

The proof of global convergence for Rosen's method for convergent generated sequence is based on the second slope lemma [6]. In general, several lemmas motivated from properties of slope are very interesting and helpful in establishing the global convergence of feasible direction methods.

SOME DEVELOPMENTS

Since Zoutendijk's method and Wolfe's method do not hold the global convergence when generated sequence is not convergent and the global convergence of Rosen's method

was an open problem for a long period, one discovered many variations [10–20,21] about them to improve their convergence. This research direction was very active 25 years ago. Meanwhile, one tried to improve their convergent rate by introducing various variable metric methods and conjugate gradient methods into feasible direction methods [15–17,22–25,28–30]. Those variations have superlinear convergent rate. While the feasible direction method is well-studied for linear constraints, their extensions to nonlinear constraints is also developed extensively [21–26].

FEATURE EXTRACTION AND FEATURE SELECTION: A SURVEY OF METHODS IN INDUSTRIAL APPLICATIONS

MICHEL J. ANZANELLO

Department of Industrial Engineering,
Federal University of Rio Grande do
Sul, Porto Alegre, Brazil

The feature selection problem, also known as variable selection, is deemed one of the most challenging problems in statistical applications. Consider a set of J variables describing a hypothetical process or situation; many of these J variables do not contribute to any inference, such as model building or classification procedure. The challenge consists of defining a subset of p relevant variables, $p < J$, carrying most of the important information with minimal noise.

Problems related to high volume of data have become evident in many segments. In statistical and mathematical applications, where the goal is usually to find a model yielding good prediction on the response variable, the excessive number of predictors might only add noise to the model. These problems can be extended to chemical and industrial processes, where the increasing use of sensors for process monitoring and the widespread availability of computational resources have made the handling of large amounts of data a challenging task [1]. Hundreds or even thousands of noisy and correlated process variables are collected on a minute basis for monitoring and control purposes. Such volume of data may jeopardize the accuracy of process control activities.

Selecting process variables in industrial applications is an important effort for several reasons. A model composed of a large number of variables may fit well to historical data, but it does not assure high performance in terms of prediction or classification due to overfitting [2,3]. Overfitting occurs in excessively complex models (i.e., presenting too many degrees of freedom); an

overfitted model tends to describe mostly random error or noise instead of the underlying relationship. Second, identification of important variables based on engineers' empirical knowledge may or may not be correct. Third, variables that are noisy, due to sensor and other problems, may lead to a confusing or misleading model. Finally, it is preferable to have a parsimonious model for easier data collection and analysis.

It appears that the nature of data and field of application dictate the best statistical techniques to select variables. Variable selection approaches in industrial applications have ranged from very basic selection techniques, for example, stepwise, backward, and forward [4,5], to more complex multivariate techniques, such as partial least squares (PLS) [6–8], data mining tools [9], principal component analysis (PCA), and clustering [4], among others, and optimization tools, such as linear programming and genetic algorithms (GAs) [5,10].

Another widely applied technique for dimensionality reduction in practical applications is the feature extraction, or variable extraction. Apart from variable selection, which retains only a subset of significant variables, variable extraction actually transforms the variable. It projects the original dataset with higher dimensionality onto a smaller number of dimensions using linear or nonlinear combinations of the original variables [11]. This yields a much smaller and richer set of variables, which becomes particularly useful for data visualization such that a complex dataset can be visualized efficiently when reproduced in two or three dimensions. Models built on extracted variables usually present higher predictive quality than models built on original variables since the data is described by fewer, more meaningful new variables.

A few applications of variable extraction include analysis on data compression, decomposition and projection, pattern recognition [12], image processing [13], and biomedical applications [14]. Although applied on

industrial scenarios, this article is tailored to the variable selection problem.

For the objectives of this article, we assume there are two main purposes for selecting variables: (i) variable selection for prediction, where one aims at finding a limited subset of process variables, x , leading to the best prediction of response variable, y ; and (ii) variable selection for classification, where the goal is to identify the subset of process variables with the best discriminative ability to categorize observations in classes. Some approaches related to these two purposes are briefly described in the following sections.

VARIABLE SELECTION FOR PREDICTION

Consider the relation between a set of J process variables, $x_1, \dots, x_J$, and a response variable y represented by the generic multiple linear regression (MLR) model in Equation (1). The goal is to identify a set of p process variables, $p < J$, able to better explain and predict the response variable y

$$y = \sum_{i=1}^J b_i x_i. \quad (1)$$

Simplistic approaches for variable selection in MLR rely on backward, forward, and stepwise methods. In the backward multiple regression method (BMR), an initial model with J variables is constructed and a significance test, such as F or p value, is performed on the regression coefficients. The variable with the smallest F (or largest p value) is removed and a new regression based on $J - 1$ variables is generated. The process is repeated until the remaining variables have an F value larger than a defined threshold. The resulting variables are then used in the prediction model. Forward multiple regression (FMR) is similarly guided by a significance test, but variables are now introduced one-by-one in the model. The stepwise multiple regression (SMR) is a combination of the FMR and BMR, where variables can either enter or leave the model, based on specific thresholds [15–17]. These

methods have also been used as a reference to evaluate the performance of recent methods for variable selection, as in Xu and Zhang [5], Chong and Jun [6], and Anzanello *et al.* [9].

In addition, several criteria have been developed to evaluate the impact of adding/removing variables in MLR models. Some of these measures include Akaike's criterion (AIC) [18] and Schwarz's Bayesian criterion (SBC) [19], which penalize models when process variables are added. Similarly, the PRESS (prediction sum of squares) criterion assesses how prediction is affected when variable i is momentarily omitted from the model; this procedure is similar to the leave-one-out-at-a-time analysis. The variable yielding the worst PRESS is removed, such that the model has a better predictive ability when that variable is left out; the procedure is repeated for the $i - 1$ remaining variables and the PRESS is continuously monitored [17].

The prediction quality of basic regression models, such as the MLR, may be highly affected by industrial data, where variables, frequently, are correlated and noisy, and may present missing values and more variables than observations [1,20]. These conditions affect the estimation of regression coefficients and jeopardize the quality of variable selection generated by BMR, FMR, and SMR techniques, yielding imprecise predictions. An alternative regression technique capable of handling this sort of data is the PLS regression, described in the following section.

Variable Selection in PLS Regression

Owing to its robustness in handling ill-conditioned data, the PLS regression became the main tool for prediction in manufacturing and chemometrics applications. PLS is an iterative regression that generates linear combinations of process and response variables, aiming at maximizing the covariance between these combinations. For further information on PLS regression and its parameters, see Wold *et al.* [21,22]; a discussion on the properties of PLS and MLR is reported by Almoy [23] and Dingstad *et al.* [24].

Although more robust than the MLR, irrelevant and noisy variables also endanger the predictive ability of the PLS regression, which justifies the large number of methods aimed at identifying the most relevant variables for use in that regression. The general approach consists of applying statistical tools to the original dataset in order to prescreen and select relevant variables, and then using the resulting subset of variables in a PLS regression model for prediction [4]. In some applications, the subset selected by a statistical tool is refined using the PLS regression coefficients and a smaller subset is effectively used on the final model.

Some industrial segments are well known for developing and applying variable selection methods in PLS regression: Wang *et al.* [25] in refinery processes; Wold *et al.* [21] in paper recycling; Hoskuldsson [26] and Xu *et al.* [27] in near-infrared data; and Baumann *et al.* [28] and Zhai *et al.* [29] in quantitative structure–activity relationship/quantitative structure–property relationship (QSAR/QSPR). PLS has also been combined with a large variety of multivariate and optimization techniques for variable selection, as reported by Gauchi and Chagnon [4]; Xu and Zhang [5]; Chong and Jun [6]; and Huang and Wang [10]. We now briefly present some of these methods.

Gauchi and Chagnon [4] performed an extensive comparison of methods for variable selection using PLS regression in five datasets of chemical processes. The best method suggested by these authors is named backward- Q^2_{cum} (BQ). The index Q^2_{cum} is a measure between 0 and 1 of the predictive performance of the model (values close to 1 denote better predictions). The BQ method initially constructs a PLS model using the J process variables, evaluates Q^2_{cum} , and eliminates the variable with the smallest absolute PLS regression coefficient. A new PLS is created using $J - 1$ variables, Q^2_{cum} is again measured, and a new variable is eliminated. This procedure is repeated until there are no remaining variables. The final subset of variables is the one with the maximum Q^2_{cum} .

Another simple and efficient method presented in Ref. 4 is named simple regression

(SR). The response variable (y) is regressed against each of the J process variables one at a time, generating J regression coefficients. A test of significance on each of these coefficients defines the variables that will be used as predictors in a PLS model.

In a similar context, Chong and Jun [6] proposed a comparison between three methods for variable selection in a steel production plant: PLS-VIP (i.e., PLS regression associated to a variable selection importance index, the Variable Importance for the Projection), Lasso regression (LR) and SMR variable selection methods. The methods were tested in simulated datasets generated by the following simulation factors: (i) proportion of important variables, (ii) magnitudes of correlations, (iii) structure of regression coefficients, and (iv) noise. These authors found PLS-VIP as the best method for variable selection.

Some variable selection methods utilize the information on PLS regression parameters to iteratively identify the most relevant variables. Sarabia *et al.* [30] suggested a graphical method based on the reweighting of selected elements in the PLS weight vector, using cross-validation to evaluate the quality of predictions generated by the model. Forina *et al.* [31] proposed the sequential updating of relevant process variables by using an important vector obtained in a previous iteration. Variables with little information were given small weights, reducing or eliminating the influence of irrelevant variables. In Zarzo and Ferrer [32], a variable selection approach to evaluate variability on the product variable is proposed and compared to a blocked PCA approach. Lazraq *et al.* [33] suggested two inferential variable selection methods in PLS regression, namely PLS-Forward and PLS-Bootstrap, and compared those to the best methods in Ref. 4. These authors stated that there is no unanimous variable selection method, and a combination of methods should be used to corroborate a final subset.

PLS has also been utilized for selecting the most relevant variables in near-infrared (NIR) data, where datasets may present thousands of process variables. Hoskuldsson [26]

suggested the removal of process variables that present low correlation with y before applying PLS, yielding a more stable regression model. In addition, Xu *et al.* [27] utilized weighting vectors to calibrate the contribution of each process variable in NIR data during PLS iterations. Such weighting vectors are estimated by means of particle swarm optimization (PSO), an optimization technique that finds a solution for a problem in a search space. As for Fourier transform-infrared (FT-IR) spectral data, Leardi *et al.* [34] applied GAs to identify relevant variables, which are then used in a PLS model aimed at improving prediction of additive concentrations in polymer films. The method proposed in Ref. 34 also reduces the probability of overfitting the PLS model. Other approaches in infrared data can be found in Duranda *et al.* [35], Ye *et al.* [36], and Teofilo *et al.* [37].

Another field where variable selection has become an issue is the QSAR/QSPR analysis. QSAR/QSPR is defined as the process by which the chemical structure of a substance is correlated with a well-known process (e.g., chemical reactivity or biological activity). For instance, chemical reactivity of a certain substance can be expressed as the amount of that substance required to obtain a chemical response. Such quantitative representation enables precise characterization of substance properties and reduces costs of analyses. Variable selection approaches in QSAR/QSPR aim at selecting the most relevant variables for describing such chemical reactivity. For that matter, Zhai *et al.* [29] used a combination of PLS and projection pursuit (a technique that projects a high-dimensional dataset into low-dimensional subspace; see Ref. 38) to reduce the number of variables for explanation of chemical products. In addition, Baumann *et al.* [28] combined PLS, PCA, and tabu search to evaluate the prediction quality of models after variable selection. Finally, Roy and Roy [39] integrated PLS, k -means clustering technique and several coefficients of regression adherence to identify the best subset of variables in a predictive model. Other QSAR/QSPR related variable selection

procedures are reported in Liu *et al.* [40] and Gonzalez *et al.* [41].

Variable Selection and Other Tools for Prediction

Although PLS regression covers most of the predictive role in manufacturing and chemometrics applications, other statistical tools have been used to select variables with that purpose. Xu and Zhang [5] found that GAs and leaps-and-bounds performed better than the traditional SMR, FMR, and BMR methods in chemical data describing nitrobenzene toxicity. The selected variables could then be used in MLR or artificial neural networks to predict substances toxicity. With similar purposes, Gualdron *et al.* [42] suggested an efficient two-phase method to select variables in gas sensing applications. The first phase estimates a “figure of merit” index for each variable; variables whose indices are below certain threshold are removed. The second phase applies GAs and other stochastic approaches on the remaining variables to identify important variables, which are then used to build neural predictive models.

Another regression technique yielding higher performance after variable selection is the LR. Regression coefficients of the LR are estimated by weighting the PRESS toward a “shrinking parameter.” This parameter defines the variables included in the regression model by forcing coefficients of less important variables to assume zero value. The LR as variable selection method was applied to steel manufacturing data by Chong and Jun [6]. For details on LR fundamentals, see Refs 43 and 44.

Additional approaches for variable selection with prediction purposes include the use of GAs, as in Chatterjee *et al.* [45], and Gualdron *et al.* [46]; and Bayesian methods, as in Philips and Guttman [47].

Table 1 depicts a summary of the most cited approaches for variable selection with prediction purposes based on their mathematical background. Studies combining two or more techniques are listed under all used techniques.

Table 1. Summary of Approaches for Variable Selection with Prediction Purposes

PLS Regression	Variable Selection for Prediction		
	Genetic Algorithm	Stepwise	Clustering
Gauchi and Chagnon [4]	Leardi <i>et al.</i> [34]	Xu and Zhang [5]	Gauchi and Chagnon [4]

VARIABLE SELECTION FOR CLASSIFICATION

In several manufacturing processes, the objective of variable selection is not prediction, but classification of observations into classes regarding some final specification, such as quality, level of profitability, or product reliability. Such observations usually refer to production batches or lots. A proper classification procedure, especially during the early stages of the process, allows adjustments on the process parameters to correct inconsistencies or, in many cases, enables the assignment of the product to a specific destination.

Most variable selection approaches with classification purposes rely on the combination of data mining tools and discriminant functions, and are usually focused on (i) improving the classification ability of existing algorithms, and (ii) reducing the processing time of the algorithm using a small subset of variables. Assessment of classification performance attained by such methods usually relies on measures such as accuracy, sensitivity or specificity, among others [12].

There are many examples of successful methods and approaches using data mining tools for variable selection in literature. A comprehensive theoretical survey of variable selection approaches is reported in Liu and Yu [48], while a comparison of algorithms for that purpose is presented by Kudo and Sklansky [49]: the best method combines leave-one-out rule and k -nearest neighbor

(KNN) classification technique. A method for variable selection and classification of observations into two classes relying on PLS regression and kernel was proposed by Tenenhaus *et al.* [50]. Although simple and easy to implement, the performance of the proposed method is equivalent to more complex data mining tools, such as support vector machine (SVM). Additionally, Krzanowski [51] and Glen [52] use discriminant analysis to select variables from a mixture of continuous and discrete variables, while variable selection approaches are combined with discriminant analysis by Pacheco *et al.* [53].

Anzanello *et al.* [9] proposed a method to select variables for classification of production batches in two quality levels in chemical processes. The framework integrated PLS regression and data mining tools, as KNN, SVM, and probabilistic neural network. The proposed method remarkably reduced the number of variables needed for classification, whereas yielded significant more accurate categorizations. The method was also innovated by developing new indices of variable importance for the classification purpose: these indices guide the variable removal process according to its impact on classification accuracy. Another variable selection framework was proposed by Anzanello [54] aimed at improving clustering results in a shoe manufacturing process. The original set of variables consisted of two groups of variables: (i) a set of process experts' variables

subjectively assessing the product complexity, and (ii) a set of learning related variables represented by the parameters of the learning curve (for details on learning curves, see Teplitz [55]). Variables were selected using a leave-one-variable-out-at-a-time, and the performance of the clustering procedure evaluated by means of the silhouette index. Clustering performance was improved significantly by using a reduced combination of the two sets of variables.

Some classical approaches for variable selection arise from the food manufacturing industry. Several approaches use PCA to identify the variables with most variance and then apply tools for classification (e.g., data mining, discriminant and clustering techniques) using the selected variables [56,57]. A method to reduce dimensionality in industrial wine manufacturing was reported by Urtubia *et al.* [58]: PCA was first used to select the variables carrying most of the metabolite interaction information, and classes of similar behavior were then generated by applying *K*-means clustering technique on the lower-dimensional dataset. In Camara *et al.* [59], PCA was associated to discriminant analysis to differentiate and classify wines; coefficients of discriminant functions were used to identify the relevant variables.

A similar study was conducted by Rebolo *et al.* [60] for testing the authenticity of wines produced in a specific region. Variables describing chemical substances were initially selected using cluster analysis and PCA techniques, followed by a stepwise Bayesian analysis. The study also aimed at categorizing the wines in classes according to their origin. With identical purposes, Marini *et al.* [61] studied two classification techniques, that is, soft independent modeling of class analogies (SIMCA) and UNEQ, to verify the authenticity of Italian wines. SIMCA describes the similarities among the samples of a category using a PCA [62], while the UNEQ is similar to a quadratic discriminant analysis [63]. The identification of the relevant variables was performed by means of stepwise linear discriminant analysis. In Capron *et al.* [64], a wine dataset consisting of 63 process variables was evaluated using

decision trees and modifications on PLS regression to identify the most important variables aimed at classifying wines into four different classes (i.e., origin countries). Also, in the food industry, integrated PCA, KNN, and Crombach's alpha are used to identify both the most relevant sensorial variables and the most consistent panelists in sensorial evaluations. The proposed method significantly reduced the number of sensorial variables needed for categorization of food samples into eight classes, besides reducing the number of panelists needed for assessment.

Other interesting applications of variable selection approaches might not be closely related to manufacturing or chemometrics, but could be easily adapted to such purposes: Chen *et al.* [65] integrated flexible neural trees to GAs aiming at identifying the important variables in breast cancer classification, while Chaovalitwongse *et al.* [66] used the KNN classification technique on time-series data of patients with abnormal brain activity. King and Jackson [67] tested four methods of variable selection based on PCA and Procrustes analysis in large environment-related datasets. Finally, a method for selecting gene-related variables was proposed by Diaz-Uriarte and Andres [68]; the method used random forest technique, and had comparable performance for classification of methods such as KNN and SVM.

The multicriteria variable selection using data mining tools has also received crescent attention in recent years. In these applications, sensitivity, specificity, and precision, among other performance measures, are simultaneously used to evaluate the prediction/classification performance. Li and Li [69] used sensitivity and specificity to select variables in biomedical applications. The same criteria were used by Su and Yang [70] in combination with SVMs to help in diagnosis of hypertension. Kirkos *et al.* [71] propose the combination of decision trees, neural networks, and SVM to select the most important variables in economic applications, while Gaganis *et al.* [72] compare KNN technique with discriminant analysis in financial evaluations. Other applications can be found

in text recognition, business decisions, and security systems [10,69,73–75]. As seen, the application of multicriteria approaches for variable selection in manufacturing and chemometrics applications is very incipient, and research on that topic is been currently developed by this author.

Table 2 depicts a summary of the most cited approaches for variable selection with classification purposes based on their mathematical background. Studies combining two or more techniques are listed under all used techniques.

CONCLUSION AND SUGGESTIONS FOR FUTURE RESEARCH

The variable selection problem became a capital issue in many industrial processes due to the high volume of data collected by sensors and experiments, leading to a broad variety of efficient methods to identify the most relevant variables. This article briefly described methods to select the most relevant variables on manufacturing and chemometrics applications. For convenience, we deployed the presentation into two classical purposes of variable selection: prediction and classification. Variable selection for prediction has been mostly accomplished by means

of the PLS regression and other statistical tools, while methods focused on classification have integrated data mining and discriminant analysis to dimension reducing techniques, such as PCA, among others.

It seems that the search for efficient combinations of statistical techniques dictates the trend for future variable selection methods. One such promising approaches might be the insertion of parameters from regression models (e.g., PLS, MLR, LR) into data mining and optimization tools to calibrate variables during the selection process. Such parameters will capture relevant information on the variance of process and product variables, which might be used to penalize irrelevant variables before applying the selection method itself.

Techniques of set pruning might also be helpful in datasets consisting of several hundreds of variables. A possible approach would consist of two phases: a first phase would filter the original dataset to eliminate variables that do not contribute on model construction. A second phase would focus on the identification of the best subset among the remaining variables using either optimization techniques, for example, GAs, or approaches based on the leave-one-out-at-a-time analysis, among others. These approaches tend to be computationally more efficient than using the entire original set,

and could avoid the occurrence of local optimal solutions.

Efforts on multicriteria variable selection also pose a challenging proposition; methods will have to select variables assessing simultaneous criteria, for example, accuracy performance and costs of collecting/measuring variables. These methods should also incorporate experts' assessment on the selection process.

Finally, the availability of so many variable selection procedures and fields of application has offered some pitfalls for researchers and practitioners, as reported in Ref. 77. Many methods have yielded remarkable results when applied to specific fields, but failed on slightly different processes by misleading the variable selection and yielding conflicting results. This has caused some practitioners to use old-fashioned variable selection techniques, such as SMR and AIC, instead of applying the most recent methods. Studies on the robustness of recently proposed variable selection methods are mandatory to better understand their properties and ensure general application.

FICTITIOUS PLAY ALGORITHM

PABLO ZAFRA
Department of Mathematics,
Kean University, Union,
New Jersey

While a linear programming (LP) formulation may allow us to find an exact solution to matrix games, it is not always necessary (or practical) to find this exact solution particularly for a large payoff matrix (see **Linear Programming and Two-Person Zero-Sum Games**). There are game-theoretic methods that have been proposed: the numerical method of von Neuman [1], the differential equation approach of Brown and von Neuman [2], and the fictitious play method of Brown [3]. Brown's fictitious play method is particularly appealing because of its simplicity, which does not require heavy computation or calculation. It is an iterative procedure that provides an estimate of a solution to matrix (two-person zero-sum) games, albeit on a rather very slow rate.

When first proposed, the method was not known to converge, but it was applied to a few games with success. Convergence was proved soon after by Robinson [4], who showed that the strategies generated by fictitious play for both players yield game value approximations that converge to the true value of the game as the number of plays (iterations) becomes infinite. She did not, however, provide a rate of convergence. Brown suggested in his paper that the rate could be of order $O(1/k)$, but further computational experiments by Zafra and Peterson [5] suggests a slower rate of order $O(\sqrt{k})$, which follows Szép and Forgó's conjecture [6].

Gass *et al.* [7] later introduced an improvement to the fictitious play method. Their modified fictitious play (MFP) method exhibits a convergence rate that is much superior to the standard form. Washburn [8] provided further refinements of MFP that appear to converge even faster.

Although Brown's original method was developed for solving matrix games, various forms of fictitious play algorithms arose in the literature as researchers applied the concept to different classes of games such as nonzero-sum, n -person, and continuous-type games. A survey of the literature on these variants is presented in the section titled "Fictitious Play and Other Games."

BROWN'S FICTITIOUS PLAY METHOD

We assume an $(m \times n)$ payoff matrix $A = (a_{ij})$, where the a_{ij} represents the payment of P2 to P1. Denote the i th row of A by A_i and the j th column of A by A^j . Let $X = (x_1, \dots, x_i, \dots, x_m)$, $\sum x_i = 1$, $x_i \geq 0$ be a mixed strategy vector for P1, and let $Y = (y_1, \dots, y_j, \dots, y_n)$, $\sum y_j = 1$, $y_j \geq 0$ be a mixed strategy vector for P2. If some $x_i = 1$ ($y_j = 1$), then the corresponding strategy vector for P1 (P2) is termed a *pure strategy* and is denoted by X_i (Y_j).

Brown's iterative fictitious play method can be viewed as a statistician's way of solving matrix games, where a player will base future moves on his opponent's historical tendencies. As Brown pointed out, the method "... rests on the traditional statistician's philosophy of basing future decisions on the relevant past history." The procedure can be characterized as follows [9]:

Two players, perhaps unaware of the minimax theorem, engage in playing the same two-person zero-sum game repeatedly. They apply a greedy policy for choosing a particular pure strategy in each play which is based on the following intuitive consideration: each player chooses a strategy that is best against his opponent's past actions, relying on a statistician's belief that future actions will resemble the past. The relative frequencies of the pure strategies used in the plays provide estimates for the mixed strategies.

We now describe the method formally.

Let k be the index count of the number of iterations; we start with $k = 0$. For any

$(m \times n)$ matrix game A , we define two vectors $U(k) = [U_1(k), \dots, U_i(k), \dots, U_m(k)]$ and $V(k) = [V_1(k), \dots, V_j(k), \dots, V_n(k)]$, with $U(k)$ a column vector and $V(k)$ a row vector. U and V are the payoff vectors for P1 and P2, respectively. The process is initiated with $U(0) = (0, \dots, 0)$ and $V(0) = (0, \dots, 0)$. For $k = 1$, P1 arbitrarily plays the i th row and we form $V(1) = V(0) + A_i$. P2 would respond by playing column j , where $j = \operatorname{argmin}[V_1(1), \dots, V_n(1)]$. We then form $U(1) = U(0) + A^j$. This completes the first iteration.

In subsequent iterations k , P1 plays row i corresponding to $i(k) = \operatorname{argmax}[U_1(k-1), \dots, U_m(k-1)]$ and P2 plays column j corresponding to $j(k) = \operatorname{argmin}[V_1(k), \dots, V_n(k)]$. The vectors U and V are updated by the formulas

$$\begin{aligned} U(k) &= U(k-1) + A^{j(k)}, \\ V(k) &= V(k-1) + A_{i(k)}. \end{aligned}$$

For any $k \geq 1$, we see that the vectors $U(k)$ and $V(k)$ are the cumulative payoffs to P1 and P2, respectively, against the other player's set of iterative strategies. That is, if $a_i(k)$ is the number of times P1 has played strategy i and $b_j(k)$ is the number of times P2 has played strategy j , then

$$\begin{aligned} U(k) &= \sum_j b_j(k) A^j, \\ V(k) &= \sum_i a_i(k) A_i. \end{aligned}$$

For each iteration, the fictitious play method directs P1 to select row i that maximizes the payoff against P2's mixed strategy to date, while P2 would respond by selecting column j which minimizes his payout to P1. Ties are broken arbitrarily. At the end of the k th iteration, the mixed strategy vectors for P1 and P2 are $X(k) = (a_1(k)/k, \dots, a_m(k)/k)$ and $Y(k) = (b_1(k)/k, \dots, b_n(k)/k)$, respectively. Robinson's convergence theorem [4] showed that, for k large enough, $X(k)$ and $Y(k)$ approximate the optimal strategies. Moreover, note that for the vector $U(k)/k$, its maximum component, say $M(k)$, is an upper-bound estimate for v , since P2 can

select any strategy among the columns j and keep P1's expected earning to be at most $M(k)$. While for the vector $V(k)/k$, its minimum component, say $m(k)$, is a lower-bound estimate for v , since P1 can select any strategy among the rows i and make P2's expected payout to be at least $m(k)$. That is, $m(k) \leq v \leq M(k)$ [10].

Since convergence is not finite, the method terminates when (i) the specified iteration limit has been reached, or (ii) the desired precision for the game value error estimate (the difference between $m(k)$ and $M(k)$) has been achieved.

Example. To demonstrate Brown's fictitious play method, we reproduce in Table 1 the payoff matrix from his paper [3]:

Using a transformation to a linear program [11] (see **Linear Programming and Two-Person Zero-Sum Games**), we found that the game has value 1.441667 with the optimal mixed strategies $X = (0, 0.12037, 0.237037, 0.642593)$ and $Y = (0.083333, 0.666667, 0.25)$ for P1 and P2, respectively.

Summary of calculations for the cumulative payoffs for the first 25 steps of the algorithm are shown in Table 2. Note that $\Delta(k) = M(k) - m(k)$ in the table.

At $k = 0$, we initialize $U(0) = (0, \dots, 0)$ and $V(0) = (0, \dots, 0)$. To start constructing the table with the iteration $k = 1$, suppose P1 arbitrarily plays row 2 ($i = 2$). We form the payoff vector $V(1) = (1.3, 2, 0)$ from which P2 responds by playing column 3 ($j = 3$) to minimize his payout. We then form the payoff vector $U(1) = (1.2, 0, \underline{3.1}, 1.1)$. This completes the first iteration. Note that the underlined components in both vectors mentioned above will be used to calculate the lower and upper bound values of the game value. For

Table 1. Brown's Game Matrix

this iteration $k = 1$, we have $m(1) = 0/1 = 0$, which is obtained by using the minimum component of $V(1)$, and $M(1) = 3.1/1 = 3.1$, which is obtained by using the maximum component of $U(1)$. Recall that $m(k)$ and $M(k)$ provide the lower bound and upper bound values for the game value, respectively.

In the next iteration ($k = 2$), P1 looks at $U(1)$ and plays row 3 ($i = 3$) to maximize his reward. The vector $V(2) = V(1) + A_3 = (1.3, 2, 0) + (0, 1, 3.1) = (1.3, 3, 3.1)$ is thus formed. P2 responds by playing column 1 ($j = 1$) to form the vector $U(2) = U(1) + A^1 = (1.2, 0, 3.1, 1.1) + (3, 1.3, 0, 2) = (4.2, 1.3, 3.1, 3.1)$. This completes the second iteration. Note that we now have $m(2) = 1.3/2 = 0.65$, the minimum component of $V(2)/2$, and $M(2) = 4.2/2 = 2.10$, the maximum component of $U(2)/2$. This completes the second iteration $k = 2$ as seen in the table.

The step is then repeated until the desired index is reached ($k = 25$ for this example) or

a desired accuracy is achieved in regards to $\Delta(k)$, the difference between $M(k)$ and $m(k)$. After 25 iterations, we see that $m(25) = 1.40$ and $M(25) = 1.47$. Observe that the values of $m(k)$ and $M(k)$ are not monotonic and they jog around the game value of 1.441667. This illustrates a typical behavior of the method.

After 25 iterations, the estimate for P1's mixed strategy can also be calculated by $X(25) = (4/25, 5/25, 7/25, 9/25)$, since row $i = 1$ has been played 4 times; row $i = 2$, 5 times; row $i = 3$, 7 times; and row $i = 4$, 9 times. For P2, the estimate for the mixed strategy is given by $Y(25) = (4/25, 14/25, 7/25)$, since column $j = 1$ has been played 4 times; $j = 2$, 14 times; and $j = 3$, 7 times. With only 25 iterations applied so far, observe that these are indeed very rough estimates of the optimal mixed strategies mentioned earlier. However, if large number of iterations are executed, say 10,000 iterations, the mixed strategies obtained are given by

$X = (0.0015, 0.1183, 0.2354, 0.6448)$ and $Y = (0.0843, 0.6652, 0.2505)$, which are fairly close to the optimal strategies.

Moreover, after 25 iterations, we find that $m(k)$ and $M(k)$ approach the game value somewhat rapidly with $m(25) = 1.40$ and $M(25) = 1.47$. However, at the end of 10,000 iterations, we found that $m(10,000) = 1.44071$ and $M(10,000) = 1.44192$ which gives error precision of only about 0.001, a slight improvement over the error 0.07 after only 25 iterations.

This illustrates another typical behavior of the algorithm, which gives seemingly fast convergence during early iterations but tends to drag later on. The convergence is painfully slow if extreme precision is desired. However, the method does provide a good approximation if high accuracy is not required, which is often true in practical applications.

CONVERGENCE AND MODIFICATIONS

Although the method has been proved to converge by Robinson, the rate of convergence is very slow. Shapiro [10] gives a rate of convergence estimate for fictitious play in terms of how fast $\Delta(k)$ goes to zero as k goes to infinity. His *a priori* estimate of the rate of convergence is of order $O(k^{-1/(m+n-2)})$ for an $(m \times n)$ general payoff matrix, which is rather loose. Shapiro suggested that this convergence rate could be improved. Brown actually suggested in his original paper that the rate could be of order $O(1/k)$. Szep and Forgo [6] later conjectured that the rate of convergence for a general game can be sharpened to $O(k^{-1/2})$. Further computational experiments by Zafra and Peterson [5] are consistent with Szep and Forgo's conjecture.

The first modification of the method was mentioned by Robinson in her proof [4], where she constructs a description of the fictitious method with the two players updating their beliefs (i.e., pure strategies) simultaneously rather than in an alternating manner. She then provided Brown's proposed method as an *alternate notion* of her vector system. However, she clearly pointed out that her proofs and results hold for both versions of the fictitious play method. It

turns out that this "simultaneous" version of the fictitious play is not as fast in empirical experiments compared to Brown's originally proposed sequence of alternate plays [5].

Gass *et al.* (GZQ) [7] later introduced a simple modification of Brown's method for symmetric games that greatly improved the convergence rate. If the original game is not symmetric, the basic idea is to transform the given general matrix game into an equivalent symmetric game (a game with a skew-symmetric matrix, that is, $a_{ij} = -a_{ji}$ for all i, j) and use the solution properties of symmetric games (the game value is zero and both players have the same optimal strategies). The symmetrization is done by using Gale, Kuhn, and Tucker's transformation matrix below [12]:

$$S = \begin{bmatrix} 0 & A & -1 \\ -A^T & 0 & 1 \\ 1^T & -1^T & 0 \end{bmatrix},$$

where A^T is the transpose of the given general $(m \times n)$ payoff matrix, 1 is a column vector of 1's with the appropriate number of components, and 0 is composed of zeros to fill out the matrix.

The fictitious play method is then applied to the enlarged skew-symmetric matrix with a modification that calls for the periodic restarting of the process. At restart, both players' strategies are made equal based on the following considerations: Select the maximizing or minimizing players' strategy that has a game value closest to zero. For both symmetric and general games, their modified fictitious play (MFP) procedure, where only the more successful player's strategy is retained, approximates the value of the game and optimal strategies in a greatly reduced number of iterations and in less computational time when compared to Brown's original method.

Limsakul [13] proposed a dynamic approach to the MFP method that involves a generalization of the matrix S above. It should first be noted that the solution to S requires that the matrix game A has a positive value. To meet this requirement, GZQ simply added a constant to all the entries of A . Although this *static* addition ensures

positive game value, they also suggested that a dynamic approach would produce better results. Following this suggestion, Limsakul used a dynamic procedure where the current best lower bound on the value of the game is subtracted from every entry. Note that this lower bound is necessarily negative because S is a symmetric game, and therefore subtracting this negative lower bound from the matrix entries would result in a modified matrix that has a small but nonnegative value. He reported a better computational experience compared to MFP.

Washburn [8] further extended and improved MFP by introducing not only a generalization of the matrix S but also a *minimal* symmetrization matrix B that omits the last row and column of S . The players of the game matrix B would then employ his improved MFP, in conjunction with a dynamically adjusted version of this minimal symmetric game transformation. This different symmetrization appears to be very efficient in solving for approximate solutions of general matrix games, particularly when a more accurate estimation is required.

FICTITIOUS PLAY AND OTHER GAMES

Brown originally proposed the fictitious play method to solve two-person zero-sum games. However, it can also be interpreted as a learning process whereby two (or more) players take turns playing the same finite game repeatedly, and where each player chooses a pure strategy in every turn that is a best response against the accumulated (historical) mixed strategy of the other player(s) from previous plays. This extended notion of fictitious play as a learning process has been applied to different types of games with mixed results in terms of convergence.

First, most of the research done by game theorists tried to identify classes of games where convergence holds. Berger [14] recently compiled a list of works in the literature where the fictitious play method converges. Works showing successful convergence of the method include: Miyasawa's (2×2) nonzero-sum game [15], geometric convergence proof of Miyasawa's example

[16], supermodular games with unique equilibria [17], supermodular games with diminishing returns [18], multiplayer games with identical player utilities [19], (3×3) games with strategic complementarities [20], (2×3) games [21], $(2 \times n)$ games [22], and continuous concave-convex zero-sum games [23]. More recent additions among convergent games include Berger's ordinal potential games and quasi-supermodular games with diminishing returns [24]; and his work on games with strategic complementarities [25]. Shamma and Arslan [26] also offered a "unified convergence proofs of continuous-time fictitious play" for certain special cases including zero-sum games, identical interest games, and (2×2) games.

Some of the authors above have extended Brown's discrete method to continuous version as he described in his original paper [27], and most of them have employed Robinson's modification of fictitious play [4] where players update their beliefs simultaneously. But Berger revived Brown's original fictitious play process in 2007 [14], where players update their beliefs in an alternating manner rather than simultaneously, and demonstrated that it converges to a large class of games called *nondegenerate ordinal potential games*. Convergence results are also available for other variants of fictitious play method including stochastic [28,29], (generalized) weakened form [30,31] and best response dynamics [32,33].

Although most research centered on identifying special classes of games where fictitious play converges, others have provided counterexamples demonstrating failure to converge. While Miyasawa's example showed convergence as applied to (2×2) nonzero-sum game, it has been quickly established that convergence need not apply to general nonzero-sum games due to Shapley [34]. Shapley showed a (3×3) example where the method follows a cycling process which exhibits runs of pure strategy selections that were repeated over and over again, and the lengths of runs also increase exponentially. Mixed strategies also cycled and stayed away from the equilibrium point. Sparrow *et al.* [35] recently generalized

Shapley's example by introducing a parameter that exhibits a chaotic behavior of the fictitious play. Another example was given by Foster and Young [36], who constructed an (8×8) coordination game where fictitious play did not converge to any equilibrium point. Other counterexamples showing that the method need not converge include three problems due to Jordan [37], three examples in Gaunersdorfer and Hofbauer [38], a degenerate (2×2) supermodular game with diminishing returns [39], and games with a unique and completely mixed strategy equilibrium where players use more than two pure strategies [40].

APPLICATIONS

While there are many research works available on various implementations, adaptations, modifications, and extensions of fictitious play as applied to different classes of games, very few applications regarding its use in solving problems from other disciplines or real-world problems are available from the literature. In this section, we mention some interesting and potential applications of fictitious play.

Gass and Zafra [41] described how their MFP can be used as a crash start to LP problems, namely, to combine MFP with a mathematical programming system (MPS), whether simplex-based or interior-point method. When MFP was applied to a game that was for an equivalent LP problem, it did not take many iterations to identify the variables that would be positive in the optimal LP solution. The information could then be used to form a crash basis for starting a simplex-based MPS. Similar ideas are used to generate a starting solution for interior-point methods, and in combining the MFP solution with an interior-point solution to find an optimal basic solution to a linear programming problem. Their experiments showed encouraging results in using MFP as an efficient tool for aiding in the solution of LP problems.

Garcia *et al.* [42] applied the fictitious play concept as a new procedure to find system optimal routings in dynamic traffic

networks. In formulating dynamic traffic networks as N -person games with identical interests, vehicles are treated as players and the average trip time experienced in the network as the common payoff function. Given the route choices of all vehicles, a routing mapping assigns a time-dependent shortest path from origin to destination for every vehicle. In game-theoretic viewpoint, this routing assignment is interpreted as a *best reply* of each vehicle in regard to the routing decisions of the other vehicles. Fictitious play is therefore implemented as an iterative routing-assignment algorithm such that, at each step, the time-dependent shortest paths are computed for each player based on the historical frequency of the other players' earlier routing decisions. This "decentralized" approach in producing system optimal routings yield encouraging results in their large-scale empirical experiments.

Motivated by Garcia's fictitious play approach to solve optimization problems, Lambert and Wang [43] further demonstrated its effectiveness as a heuristic optimization method. To test the fictitious play approach, they used the large-scale situational awareness simulation on "Low-Energy Electronic Design for Mobile Platforms." In this problem, mobile units keep track of each other's location over a specified period of time. The units use communication devices to broadcast their location information, and a fictitious play approach was used in designing the communication protocol. They found that the fictitious play solutions are similar to the simulated annealing approach, with comparable computational efforts and outperforming pure random search.

Lambert *et al.* [44] developed a sampled version of the fictitious play algorithm for games with identical payoffs. Calling it *sampled fictitious play*, it is a formalized approach to Garcia's fictitious play algorithm, which has also been applied earlier to their 2003 work on mobile unit situation awareness problem. They proposed this heuristic to solve any large-scale discrete optimization problems of the form $\max\{u(y) : y = (y^1, \dots, y^n) \in$

$Y^1 \times \dots \times Y^n$, where the feasible region is the Cartesian product of finite sets $Y^i, i = 1, \dots, n$. For games with identical payoff functions for players, fictitious play is viewed as a coordinate-search algorithm for optimization. They describe a way to avoid the prohibitively expensive calculations in each iteration, which are required of the best reply strategy, with an approximation based on sampling. Computational experiments were performed with their sampled fictitious play method using the dynamic traffic routing assignment and mobile units situation awareness problems as mentioned above.

On a different application, Hon-Snir *et al.* [45] analyzed a repeated first-price sealed-bid auction of a single item where the player types are known in advance. The paths generated by players are analyzed, where each player uses various classes of belief-based learning process including a generalized fictitious play scheme. In the generalized fictitious play, a player assigns a probability to the other players' bid vectors with the assumption that the opponents' next bid vector is determined from the historical (empirical) distribution of the past bid vectors. Under mild assumptions, they showed that, after a sufficiently long time, the players play an equilibrium of the one-shot auction where player's types are known. In effect, they showed that under their belief-based learning system, a repeated first-price auction behaves like a one-shot second-price auction in the long run.

FINITE POPULATION MODELS—SINGLE STATION QUEUES

INTRODUCTION

Queueing models consisting of a finite number of customers in the population arriving for service have several real-life applications including the classical machine-interference or machine–repairman model, where the number of machines that fail and are either waiting for or undergoing repair is finite. The fundamental characteristic of finite queues is that the arrival process is nonrenewal, as the calling population of new arrivals is finite. Machine failures, data packets, assembly jobs, number of calls to a trunk system, and so on, are finite and can be accommodated only if the service facility is idle, leading to a closed system. Many variations of the finite queueing model can be constructed depending on the assumptions made on the arriving population, service distributions, and queue discipline. In the following sections, we review several popular applications of finite queues.

An important application of finite queues arises in computer communication models. Consider N terminals requesting processing time by a central server. The total number of service requests from these N terminals and the amount of time the server takes to complete the tasks can be modeled using finite queues to obtain several performance measures of the system, such as server down time, idle time, and average time to process service requests. These measures play a pivotal role for decision makers to handle a variety of

issues including capacity planning for network optimization, client-server architecture models [1–3], web services scalability, and congestion control [4,5].

Another variation of finite queueing models is employed in telecommunication systems, where call arrivals requesting service are processed if the server is free. When the server is busy, all new calls are routed to a finite buffer (waiting pool) to wait a random amount of time until they reenter service or balk out of the system. Such a system is modeled as a retrial queueing system, which is discussed extensively in the article titled *Retrial Queues* and Falin and Templeton [6].

Finite queueing models are also extensively applied to the study of vacation models, most queueing models assume the continuous availability of servers, while in reality servers often take arbitrary vacations for random amounts of time and return to queue to serve waiting customers for a limited duration. A comprehensive treatment of such models can be found in Tian [7].

Finite queueing models also have strong applications in manufacturing and production systems [8,9]. They are used to study assembly systems that are closed with input buffers of a finite capacity k having dependent arrival distributions. Another application arises in fork-join queues, where several independent arrival buffers feed a service station. The assumption of the Poisson arrivals in these models is often unrealistic as input feed buffers are capacitated in buffer size. When the desired capacity of k is attained, all new arrivals are turned away. In addition, models that involve the probabilistic feedback of completed jobs into the input buffer for rework also invalidate the Poisson arrival assumption. Key performance measures of interest in these manufacturing systems include the queue length distributions of each buffer, average synchronization time, throughput of the system, idle time of the server, and so on.

Another interesting application of finite queues is in the study of reliability, where

component failures form the arrival process for servicing requests of repair and maintenance actions. The number of components in the system which can fail is finite, and the number of service requests either waiting or being repaired is also finite. Such models can be analyzed using finite population models. In many cases of reliability modeling, there is strong connection to finite population models as noted in Kavelenko *et al.* [10]. The performance measures of interest in reliability models include queue length distribution, mean waiting time, server idle time, and so on.

In the applications given above, arriving customers do not form a renewal process as they are dependent on the number of units currently in the system, which has a finite capacity. With reference to Kendall's notation, see the article titled **Queueing Notation**, an example of a finite-source model is given by $M/G/1/K/N$, which describes a single-server model with exponentially distributed arrival times and generally distributed service times. There is a maximum of K customers allowed both in service and waiting for service, and N available customers in the population to request service, which will be accommodated if the number of customers in the system is strictly less than K . The $M/G/1/N/N$ queue is a special case of the above system, where the number of allowed service requests in the system equals the number of available customers N . In the next section, we analyze $M/M/C/r/r$ queue, often referred to as *machine-repairman model*, and some key performance measures of the model.

$M/M/C/r/r$ QUEUE-MACHINE REPAIRMAN MODEL

The classical machine-repairman model (also known as *machine-interference model*, *machine-servicing models*) was developed in the late 1960s, and aimed to study the optimal assignment of repairman to service machines subject to random failures [11]. The importance of this class of model has found profound applications and extensions, many of which have been discussed above.

In simple terms, the machine-repairman model aims to obtain systems performance measures of both repairman and machines in the system, such as the average number of machine failures, throughput, number of machines in queue waiting for service, worker utilization and efficiency, and average number of idle operators among others.

Consider a system with r machines operating independently that are subject to random failures, and C repairman present to repair failed machines, with $C < r$. Assume the machine failures (arrivals) happen according to exponential distribution with rate λ , and machine repair times (service) are independent with rate μ . All machine failures are serviced according to first-come-first-served (FCFS) discipline, and serviced machines start operating upon completion of service. This model may be described as a $M/M/C/r/r$ queueing system, which is studied using birth-death process as given in Allen [12], Gross *et al.* [13], Kleinrock [14], and Trivedi [15].

Let $N(t)$ denote the number of machines that have failed at time t . Assuming that n machines have already failed in the system, the probability of a machine failure in $(t, t + \delta t)$ is given by

$$P(\text{a machine failure} | N(t) = n) = (r - n)\lambda.$$

Given that $N(t) = n$, the probability of one of the failed machines getting fixed is in $(t, t + \delta t)$ given by

$$P(\text{rectifying a failed machine} | N(t) = n) = \begin{cases} n\mu, & 0 \leq n \leq C \\ C\mu, & n > C \end{cases}.$$

The stochastic process $\{N(t), t \geq 0\}$ follows a birth-death process [13] with arrival and service rates given by

$$\lambda_n = \begin{cases} (r - n)\lambda, & 0 \leq n \leq r \\ 0, & n \geq C \end{cases}, \quad (1)$$

$$\mu_n = \begin{cases} n\mu, & 0 \leq n \leq C \\ C\mu, & n \geq C \end{cases}. \quad (2)$$

The Kolmogorov forward equations for the birth-death process are given by

$$\begin{aligned}
\frac{dP_0(t)}{dt} &= -r\lambda P_0(t) + \mu P_1(t) \\
\frac{dP_n(t)}{dt} &= -[(r-n)\lambda + n\mu]P_n(t) \\
&\quad + (n+1)\mu P_{n+1}(t) + (r-n+1) \\
&\quad \times \lambda P_{n-1}(t); \quad \text{for } 1 \leq n < C \\
\frac{dP_n(t)}{dt} &= -[(r-n)\lambda + C\mu]P_n(t) + C\mu P_{n+1}(t) \\
&\quad + (r-n+1)\lambda P_{n-1}(t); \\
&\quad \text{for } C \leq n < r \\
\frac{dP_r(t)}{dt} &= -C\mu P_r(t) + \lambda P_{r-1}(t). \quad (3)
\end{aligned}$$

In steady state,

$$\begin{aligned}
r\lambda P_0 &= \mu P_1 \\
[(r-n)\lambda + n\mu]P_n &= (n+1)\mu P_{n+1} \\
&\quad + (r-n+1)\lambda P_{n-1}; \quad \text{for } 1 \leq n < C \\
[(r-n)\lambda + C\mu]P_n &= C\mu P_{n+1} \\
&\quad + (r-n+1)\lambda P_{n-1}; \quad \text{for } C \leq n < r \\
C\mu P_r &= \lambda P_{r-1}. \quad (4)
\end{aligned}$$

Equation (4) can be solved recursively using the following relationship to obtain the state probabilities:

$$\begin{aligned}
(r-n)\lambda P_n &= (n+1)\mu P_{n+1}; \quad 0 \leq n < C \\
(r-n)\lambda P_n &= C\mu P_{n+1}; \quad n \geq C. \quad (5)
\end{aligned}$$

Solving Equation (4) recursively, we obtain the steady-state probability of having n machines failed in closed form

$$P_n = \begin{cases} \binom{r}{n} \left(\frac{\lambda}{\mu}\right)^n P_0, & 1 \leq n \leq C \\ \binom{r}{n} \frac{n!}{C!C^{n-C}} \left(\frac{\lambda}{\mu}\right)^n P_0, & C \leq n \leq r \end{cases}, \quad (6)$$

where P_0 is obtained using the normalizing condition given by $\sum P_n = 1$, or equivalently by

$$P_0 = \left[\sum_{n=0}^C \binom{r}{n} \left(\frac{\lambda}{\mu}\right)^n + \sum_{n=C+1}^r \binom{r}{n} \frac{n!}{C!C^{n-C}} \left(\frac{\lambda}{\mu}\right)^n \right]^{-1}. \quad (7)$$

Note that the steady-state probabilities in Equations (3) and (4) are applicable for any finite-source queue with exponential service, independent of the failure arrival distribution mean rate λ . The waiting time characteristics of this model can be obtained in closed-form expression based on the steady-state probabilities obtained above. In order to obtain the waiting time distribution of arrivals conditioned on n machine failures at the arrival epoch and unconditioning using the stationary probability distribution, we obtain waiting time distributions and other characteristics [13,36,37].

As noted, the arrival rates are conditioned on the state of the system with n machine failures, yet in steady state, we may express this as an unconditioned arrival rate that is commonly referred to as the *effective arrival rate* of machines is given by

$$\lambda_{\text{eff}} = \sum_{n=0}^{r-1} (r-n)\lambda P_n.$$

Performance Measures

Several key performance measures of the $M/M/C/r/r$ queue machine-repairman model are given in this section.

- Expected number of failed machines in steady state can be obtained from the definition of expectation as

$$E[L] = \sum_{n=0}^r nP_n.$$

- Average number of machines waiting in the service queue is given by

$$E[L_q] = \sum_{n=C+1}^r (n-C)P_n.$$

The associated mean waiting time from failure to recovery and the mean

waiting time in queue for service in closed form can be obtained from the above equations by employing Little formula [12,13]. It is intuitive that the number of working machines is the total number of machines less the expected number of failed machines, that is, $r - E[L]$.

- Machine utilization is the percentage of time that machines are productive/in use, and is given by the fraction of the number of working machines over the total number of machines r as

$$\rho_{\text{machine}} = \frac{r - E[L]}{r}.$$

- Repairman utilization or operator utilization is the percentage of time repairman is available to rectify machine failures. This is obtained as the sum of the expected number of failed machines being repaired by the C repairman and the sum of the probability of the number of failed machines that exceed the available number of repairman, and is given by

$$\rho_{\text{repairman}} = \sum_{n=0}^r \frac{nP_n}{C} + \sum_{n=C+1}^r P_n.$$

- The average waiting time of machines is the ratio of average number of machines waiting over the mean arrival rate times number of working machines as

$$\frac{E[L_q]}{\lambda[r - E[L]]}.$$

- The average down time of machines is the ratio of expected number of failed machines over the mean arrival rate times number of working machines as

$$\frac{E[L]}{\lambda[r - E[L]]}.$$

- The average number of idle repairman can be readily obtained using the repairman utilization as

$$\begin{aligned} C - C * \rho_{\text{repairman}} &= C(1 - \rho_{\text{repairman}}) \\ &= C \left[1 - \left(\sum_{n=0}^r \frac{nP_n}{C} + \sum_{n=C+1}^r P_n \right) \right] \\ &= \sum_{n=0}^C (C - n)P_n. \end{aligned} \quad (8)$$

- Percentage of time the machines are down (i.e., machine-interference time) awaiting service can be obtained by dividing $E[L_q]$ with the number of machines r as

$$\frac{\sum_{n=C+1}^r (n - C)P_n}{r}.$$

- Percentage of idle operators is obtained by dividing the average number of idle repairman by the total number of repairman C as

$$\frac{\sum_{n=0}^r (C - n)P_n}{C}.$$

In the next section, we discuss several extensions including parameter estimation methods and provide references to texts, survey articles, and other literature to the machine–repairman model.

EXTENSIONS AND FURTHER READING

A straightforward extension to the machine–repairman model is to incorporate general distributions for both arrival (machine failure) and service (repair) times, which have been studied by several authors [16–20]. Additional variations of the model include varying arrival and service rates [21], different types of failures, nonidentical machines [22], spare machine availability [13,23], spare machines with cold, warm, and hot standbys [24], priority queues [25–28], and server vacations [7,28]. Although closed-form solutions to the models are uncommon, many researchers have used numerical techniques to obtain the system performance measures.

In particular, a stationary distribution of number of working machines for an $M/G/1/N/N$ system was studied in Takacs [29], yet, resulted in a cumbersome evaluation of large factorials as the number of servers increased. A stable algorithm to compute these probabilities can be found in Gupta and Rao [18], and, as an alternative, many authors have analyzed the $M/G/1/N/N$ model using supplementary variables to recursively obtain the system probabilities. Likewise, embedded Markov chain techniques have also been used to obtain the probability distribution of machine down time at arbitrary time epochs.

In practice, the efficient estimation of parameters related to the machine failure (λ) and service (μ) time distributions are key to deriving meaningful performance measures. Since the machine operating and repair times are independent, maximum likelihood estimators are often employed to obtain reasonable estimates of the model parameters. Bayesian methods, however, also present an ideal alternative for inferences employing posterior distribution to approximate distributions of performance measure as given in Gaimon and Thompson [30].

In addition, we refer the readers to excellent survey articles on finite-source queueing systems and their applications [31,32], along with the books on modeling aspects and performance measures [28,33–35].

FIRE DEPARTMENT DEPLOYMENT AND SERVICE ANALYSIS

JOHN R. HALL, JR.
National Fire Protection
Association, Quincy,
Maryland

One of the biggest success stories for operations research has been models for analysis of fire department service delivery. Pioneering work in the 1960s by researchers with the Rand Institute, New York City, won every major prize the operations research community has to offer. Applications of the work in New York and other cities have led to millions of dollars in documented savings while maintaining or nearly maintaining selected measures of service quality and quantity delivered [1–4].

Within the operations research community and literature, there have been a number of additional articles, but no dramatic shifts away from Rand's approaches. In the fire service community and its literature, however, developments have proceeded along different lines. While these alternative paths have produced potentially complementary work, there has been little effort to integrate them.

A GENERAL CONCEPTUAL MODEL OF FIRE DEPARTMENT SUPPRESSION SERVICE

A comprehensive timeline for fire development and fire department intervention might include the following elements [5]:

- *Detection Time.* Time from ignition to detection of fire.
- *Reporting Time.* Time from detection of fire to report to fire department.
- *Dispatch Time.* Time from receipt of report to dispatch of fire department resources.

- *Turnout Time.* Time from acknowledgment or awareness of call by responding forces until they begin travel to the site of the emergency.
- *Travel Time.* Time for travel to emergency site from station or other starting point to the place where the fire apparatus stops.
- *Access Time.* Time for firefighters to move from the apparatus to the point where firefighting will be staged.
- *Setup Time.* Time for firefighters to set up equipment prior to application of extinguishing agents.

There is a timeline running in parallel for the fire itself:

- smoldering, which is slow burning with no visible flame;
- open flaming period, when fire grows exponentially;
- flashover, when nearly everything in the first compartment is involved in fire;
- room-to-room spread;
- floor-to-floor spread;
- damage to structural stability;
- building-to-building spread.

Reducing any part of the first timeline by one minute will reduce fire damage by an amount that reflects the speed of fire growth at that point in the second timeline and the speed with which fire can be stopped by forces interceding at that point. If the fire department arrives while a fire is still smoldering, it is not worth arriving a minute sooner because the rate of damage during smoldering is so slow and control of the fire will occur so quickly. If the fire department arrives after flashover, it may not be able to control the fire at all until the first building is burned out. On the other hand, if the flashed-over building is a shed located some distance from any other building, there may not be much life, health, or property at risk, no matter when in the

fire timeline the fire department arrives. If the building is a high-rise with many people and considerable value, the consequences of arriving later in the fire can be enormous.

Dispatch and turnout times tend to be driven by a sequence of standard tasks and actions. There is limited opportunity to shorten those times. Setup time also involves a fairly standard set of tasks, although it can vary a great deal depending on the scale of the fire on arrival.

Detection and reporting times can be highly variable. They can be influenced by the use and performance of automatic detection, alarm, and reporting equipment, which in turn can be influenced by local codes. The use of fire sprinklers can keep fires smaller for a longer period of time.

Access time can vary significantly but is rarely addressed directly by deployment analysis models. Access time can depend on the height and area of the building and the complex or lot in which it is located, as well as the location of the fire within the building, security arrangements on site, and the extent to which fire department access complies with local requirements.

HISTORY OF TRAVEL TIME ANALYSIS AND CONTROL BEFORE THE NEW YORK CITY—RAND INSTITUTE

In the United States, for most of the twentieth century, controls and objectives on fire department travel time were greatly influenced by provisions of the *Grading Schedule for Municipal Fire Protection*, developed by the National Board of Fire Underwriters and later passed to the Insurance Services Office [1]. A community's insurance rates would be affected by the community's grade, which was calculated using an index number formula approach that included points for response times.

In the 1960s and more recently, the Grading Schedule formulas were stated as *maximum* acceptable response *distances*. All considerations that would affect the magnitude of loss associated with an extra minute of response time were channeled into index type formulas for defining categories of

estimated required fire flow (water delivered per unit time), that is, the rate of water delivery that would be needed to control a design fire at the location. Maximum acceptable response distances could be set at different values based on required fire flow.

During the 1960s and 1970s, there was growing technical criticism of the Grading Schedule [6]. The insurance industry's primary concern in creating the Grading Schedule was to avoid citywide conflagrations. A schedule designed for that purpose would not necessarily be valid for the more ordinary fires that drive total fire loss. The absence of better alternative formulas was not seen as a convincing defense, because actuarial decision making seemed capable of providing better results, at least for larger communities.

What Is the Objective Function?

If you frame the analysis to minimize travel time or to optimize on some other summary statistic based on travel time, then the basic analysis will not reflect potentially large variations in loss potential per unit time and will not reflect patterns in losses (like firefighter injuries and deaths) that may have little or no correlation to travel time at all. Those other considerations will then be either factored in through weights (e.g., hazard factors for types of buildings or for subareas) or constraints (e.g., maximums for response time or distance) or decomposed analysis (e.g., hazard groups of buildings or of subareas) or ignored.

The approach that is used will in turn make a difference, possibly a significant difference, in the relative emphasis placed on the "other considerations." If they are ignored, they will receive no emphasis. If they are handled through decomposed analysis, they may be regarded as second-order or sidebar concerns. If they are handled through weights or constraints, then the analyst may be back to something that looks very much like the Grading Schedule, at least in structure if not in specific parameters and thresholds.

Between weights and constraints, the latter approach has certain advantages. A constraints approach channels the limited

data and the interpretation of that data into a relatively small number of choices—the constraints—in a manner that resembles the standards-setting process already familiar to fire departments as the usual way of doing business. A weights approach typically requires the estimation of more parameters with more precision and more extensive use of the parameters in the analysis. If you have confidence in the weights, this is good, but if you do not—or your client does not—then the analysis may seem less transparent and so less acceptable. More specifically, with constraints it is easier to, for example, factor in the limited evidence that smaller crew sizes (fewer than four firefighters) are associated with higher firefighter injury rates per fire and a heightened risk of certain fatal scenarios. Also, incident rates by subarea or individual building may be less sensitive to small quantities of fire experience data.

THE NEW YORK CITY—RAND INSTITUTE'S PRINCIPAL TYPES OF OR MODELS FOR FIRE SERVICE DEPLOYMENT ANALYSIS

If the community's street network is laid out as a perfect grid, then all locations can be converted to graph coordinates, and travel distances will be given by the sum of distance along one dimension plus distance along the other dimension (called right-angle distance in the Rand studies). If the community's street network is more varied and dense and lacks major obstacles, like a river or railroad tracks, then it may be possible to achieve straight-line travel between many or most points in the community.

With the use of multipliers, one can adjust for the general influence of curves, hills, and one-way streets. A more complex approach uses different formulas as a function of distance (right angle for short distances, straight line for long distances, combination of both for intermediate distances).

Alternatively, one can set up the road system as a network and obtain actual link distances from appropriate data. Now you can adjust for actual locations of curves, hills, one-way streets, and even speed bumps, potholes and real-time road construction work.

The shortest-path algorithm can then be used to define the path from one location to another and calculate the travel distance associated with that path.

Travel time may not be simply proportional to travel speed if you take account of the need to accelerate and decelerate at the beginning and the end, respectively, of any trip and often at other points (e.g., when rounding corners, when street conditions are poor and will not permit peak speeds, when traffic is dense). Rand developed formulas for travel time as proportional to distance for longer distances and proportional to the square root of distance for shorter distances.

Using a queueing model framework, Rand also developed Poisson probability distributions for arrival of successive fire calls and exponential probability distributions for service time required at fire calls. Because a fire station, once located, will be expected to last for decades, they also developed bases for projecting future call volume. It would be possible to vary the parameters of the exponentially distributed service times based on hazard factors or hazard categories for the destination sites.

These simple models were then extended to address the case where a new fire call comes in while the assigned first-response company is still busy at another call.

Evaluating Alternative Locations for Fire Stations

Rand's version of a fire station location model was called the *Firehouse Site Evaluation Model* (FSEM). A very similar alternative model was developed independently at about the same time by Public Technology, Incorporated (PTI) [7,8].

The community is divided into subareas by a grid structure, and the resulting subareas are then associated with nodes for a network model of the community. Each candidate location for a station is associated with a node, and each possible site for a fire call is associated with a node. Using travel times based on either formula estimates (Rand FSEM) or collected data (PTI FSLP) for all links, the user can easily calculate travel times from

any station to any node. Using either a first-response protocol (which station goes with which node) or a closest-station approach, the user can calculate a travel time distribution associated with any choice of stations and response protocols. Nodes can be weighted by hazard factors such as the required fire flow values used by the Grading Schedule or the all-fire and structure-fire incidence rates used by Rand.

Many of the simplifications used in these models are a reflection of the times. Computational power required a coarse grid, with subareas no smaller than the coverage area of one alarm box and often several times that size. There was a simplification involved in treating travel time as constant for every structure in a single subarea, but even greater variation was ignored by treating the entire subarea as having a constant hazard factor and a single standard response complement.

Initial Dispatch Policies

In addition to decisions on how many companies to have and where to locate them, fire departments also face decisions on which and how many companies to send, based on where a fire call comes from.

The choices in framing the question for analysis are similar to those involved in station location decisions. The ideal analysis would estimate differences in loss—including direct damage, casualties, and possibly other types of loss—for each of several dispatch choices. The data required to conduct such an ideal analysis would be enormous in size, and the formulas required to make it manageable are in many cases based on a very narrow evidentiary base.

Rand elected to work with two levels of incident seriousness—called *serious fires* and *nonserious fires*—which were defined in terms of the number and type of companies they would tend to require in New York. This focused the analytical question into balancing the error of sending less than what is needed to a serious fire versus sending more than what is needed to a nonserious fire. This in turn involved analysis of patterns

of calls received from various locations and diagnostic error rates from various sources of calls (e.g., telephone report of fire vs. alarm box call).

When Is the Analysis Most Worthwhile?

The Institute published detailed documentation on their application of their models in several cities. Reading these applications, it seems clear that this kind of analysis has a hard time passing a cost-benefit test unless the community is planning to change the *number* of stations. Better siting of the same number of companies will produce marginal improvements in travel time profiles, and the scant data available on the value of time does not produce estimated benefits on the same scale as the costs of analysis and station relocations.

Applications where the number of companies is being changed come in two very different types. One is a community that plans to severely cut its budget by reducing the number of companies (e.g., New York). In such a situation, Rand found analysis could substantially reduce the impact of cuts on measures of overall average service, but strong objections from affected parts of the community were still likely and would often accuse modelers of promoting or causing the cuts.

The other type is a community facing rapid population growth and a need to add companies to respond to rising service demand (e.g., Denver's experience with Rand). In this situation, analysis can show that the same service objectives can be achieved with fewer additional companies if those companies are well located. Companies that do not exist do not have political support, so those kinds of changes in plans are less likely to produce political resistance.

Is OR-based Deployment Analysis Useful Only for Large Communities?

Rand cites six cities as the pilot users of their models—New York City, Yonkers (NY), Jersey City (NJ), Trenton (NJ), Denver (CO), and Tacoma (WA). All six had over 100,000 population at the time of the studies, and all but Trenton had over 150,000 population.

Communities of 100,000 or more population account for just over one-third of the US population but for just over 1% of US fire departments, or just over 300 fire departments. These primarily big-city departments average nearly 20 fire stations per department [9]. (Populous communities include large cities and some large urbanized counties.)

Communities of 50,000–99,999 population average five stations per department, and smaller communities average even fewer. The average for all US fire departments is less than two fire stations per department. It is not clear how large a community must be or how rapidly its population must be growing in order for the likely benefits of OR analysis to exceed the costs, but in terms of the Rand models as they were when they were created, it appears that most communities would not have found them to be worth the money.

How Is Deployment Analysis Conducted Today?

The rapid increases in computer power and calculation affordability, coupled with widespread availability of global positioning geographic databases, have created a world in which the cost of this kind of deployment analysis might be within the reach of far more communities. However, the websites for the Rand Corporation and Public Technology Institute (the modern name for Public Technology, Inc.) do not offer tools or consulting services for fire department or emergency response deployment analysis. Rand keeps its many reports and publications in print, while PTI has shifted its emphasis to IT services that do not use OR type models.

If you search the Internet for fire department deployment analysis tools and consulting, you will find vendors, but the models they are emphasizing are not the ones developed by Rand and still being refined in the OR literature.

At about the same time that the Institute was working in New York, the fire service community was pursuing “master planning.” More recently, the dominant phrase has been “community risk assessment.” In both cases,

the models, methods, and formats favor unquantified flow charts and checklists, as is common with planning approaches, rather than the quantified methods of OR.

Rating Deployment as Part of Fire Department Accreditation

In the last decade, the Commission on Fire Accreditation International (CFAI) developed an accreditation protocol that included fire service deployment elements [10].

The assessment of deployment capability is channeled through “standards of response coverage,” a term borrowed from the United Kingdom. Response time objectives are set for sites based on their risk category. The protocol defines four risk categories for structures based on high or low probability and high or low consequence. The protocol also anticipates that their simple two-part separation of consequence may be elaborated into many categories.

The names given to the four risk categories make clear that the emphasis is on consequence rather than probability. High probability/low consequence buildings are called *moderate risk* while low probability/high consequence buildings are called *high/special risk*. Inasmuch as the categories are meant to generate quantities of resources and speed of response required to minimize loss, it makes sense that probability is not particularly relevant.

Recent NFPA standards provide candidate values for response time objectives [11]. NFPA 1710 includes minimum standards for resources, including personnel, required at fire calls, based on hazard. NFPA 1710 also includes response time requirements which are stated in terms of the maximum response time achieved for 90% of fire incidents. Also in 2001, NFPA published the first edition of NFPA 1720, a companion document for volunteer fire departments [12].

The CFAI protocol identifies a process for local authorities to use in setting response time and other objectives. Accreditation depends partly on the completion of the objective-setting process and partly on success in meeting objectives once set. CFAI references NFPA standards but does not require they be used as the basis for

local objectives. CFAI also includes specific examples of individual communities, with the suite of objectives they chose. While not presented as standards or default choices, these examples could take on the aura of best practices or default choices.

The consulting firms that offer deployment analysis services are set up to work to the CFAI model. In this manner, the CFAI protocol has acquired the status that the Institute models had two decades ago—a widely used complete protocol with no competitor having comparable usage, resulting in a status as de facto standard or at least starting point for any other approach that might be offered.

In 2001, the US Fire Administration (USFA) announced the availability of software for Risk, Hazard and Value Evaluation (RHAVE), a tool to be used with the CFAI accreditation protocol [13]. The core of RHAVE is an Occupancy Vulnerability Assessment Profile (OVAP), which is a menu-based, qualitatively structured procedure for assigning hazard categories. The procedure includes information on building construction, height and area, distance to other buildings, number and characteristics of occupants, on-site fire safety features and systems relative to applicable codes, relative accessibility from the outside, types of on-site activities, types (degree of hazard) and quantities of on-site combustibles, and even degree of enforcement of codes by local fire marshals and inspectors. Water demand (fire flow) is entered by the user, not calculated. The inputs are reduced to four factors—building factor, life safety factor, risk factor, and water demand factor. The sum of these four factors is the factor score, and ranges of the score map into four RHAVE categories.

Shortly after announcing the availability of RHAVE, the USFA withdrew as its supplier and tech support. It is not clear how much RHAVE is being used by CFAI, the other original sponsor.

How Could Operations Research be Applied to Fire Department Deployment Analysis Today, Given Common Practices?

An OR deployment analysis for the twenty-first century could refine the consequence/

hazard methods and concepts developed for CFAI into weights. In partnership with fire protection engineering modelers, OR modelers could develop a more quantitative and less subjective representation of hazard (loss potential) as a function of site-specific characteristics (including access time, which is still generally ignored), scenario, and travel time.

It could use the response cover objectives as alternative measures for optimization (e.g., maximize the percentage of hazard-weighted incidents with response times that meet the objectives) or as constraints (e.g., minimize average response time to hazard-weighted incidents subject to a constraint of achieving the response time objectives).

Recent Operations Research Work on Fire Department Deployment

Most OR research on the subject in the past couple of decades has not followed the path described above but has pursued one or more of the following discussed below.

Extension to Ambulances. The last several decades have seen tremendous growth in the involvement of fire departments in the delivery of emergency medical service, either staffed ambulances or emergency medical technicians on fire apparatus who will link up with the ambulances, arriving separately and possibly under a separate authority. The CFAI protocol includes objectives for emergency medical service (EMS) that parallel those for fire suppression. As of 2005, two-thirds (67%) of US municipal fire departments provided EMS service, including nearly all departments serving communities of 100,000 or more population [9]. In 1980, NFPA statistics show municipal fire departments responded to 2,988,000 fire calls and 5,045,000 medical emergency calls, for a ratio of 1.7 EMS calls to every fire call. By 2006, municipal fire departments responded to only 1,642,500 fire calls and 15,062,500 medical emergency calls, for a ratio of 9.2 EMS calls to every fire call.

Meanwhile, a robust body of OR work on ambulance location has not grown out of the

fire department deployment literature but has its roots in health-care OR applications and facility location methods generally. This means the OR modeling may not fully address calls that involve both medical and nonmedical aspects, such as a tanker truck collision which may result in a fire, a hazardous material spill endangering the environment, and a medical emergency involving trapped or injured people. However, the NFPA standards and CFAI protocols are expressed in terms of response time and percent coverage standards; this formulation is quite compatible with the approaches used in OR ambulance location models.

It is beyond the scope of this article to characterize the state of OR work on ambulance deployment. It is also unnecessary. Three review articles provide an excellent overview—one by Henderson in this encyclopedia [14], one by Daskin and Dean [15], and one by Erkut *et al.* [16]. The latter two are recent works, both of which refer to Marianov and ReVelle [17], a 1995 piece that also remains useful today.

In emergency service delivery, it is common to treat distance as a proxy for time and time as a proxy for loss. At any particular fire, property damage may grow exponentially as a function of time. At any particular fire or medical aid call, the likelihood of survival may decline nonlinearly as a function of time. Much of the evolution in fire department and ambulance deployment models may be seen as attempts to make distance a better proxy for loss. For example, a coverage model to define successful coverage not by an acceptably short distance to the site of the emergency but by an acceptably short time for units with resources sufficient to the emergency. Other aspects of state of the art models for both fire and medical aid emergency service deployment include analysis of the solution under alternative projections of patterns of future demand and incorporation of the likelihood that the nearest unit will be busy with an earlier call.

Extension to Natural Disasters and Homeland Security. Firefighters are all-purpose first responders to every type of emergency.

In recent years, there has been greater awareness of the need for deployment and response analysis for the special challenges associated with natural disasters and homeland security. Here are three examples:

- *Post-Earthquake Fire.* Unique fire challenges can arise in the aftermath of a significant earthquake, including many simultaneous fire starts, initiated by breaks in gas lines and electrical distribution lines, and significant disruptions in the road and water supply distribution networks. Normal response protocols will need to be significantly modified to reflect these conditions, and triage protocols for multiple fires will need to be implemented. The OR community has been underrepresented in work on this subject. A major flood or snowstorm can also create some of these unique challenges, reducing availability of road networks and water supply, while also creating conditions for some simultaneous fire starts.
- *Resources Diverted by a Major Incident.* Interviewing New York City fire department officials for their retrospective on the New York Rand work, Green and Kolesar learned that the Rand relocation algorithms had allowed the city to maintain “adequate levels” of fire protection throughout the city when 200 fire companies were committed to the response to the World Trade Center fires on September 11, 2001 [4]. Many other communities have been faced with threatening flood conditions from nearby swollen rivers, forcing most if not all of their emergency response forces to commit to mitigation of the natural disaster. A community may compensate by being extra careful during such a challenge, but such behavior cannot be indefinitely sustained. Therefore, the question remains of how to achieve reasonable fire protection coverage under such conditions. OR analysis could help create better pre-plans to deal with such situations.

- *Terrorist and Ordinary Non-Fire Emergency Incidents.* The 1995 Sarin gas terrorist attack in the Tokyo subway system and the events of September 11, 2001, heightened concerns about all types of possible terrorist attacks, including chemical, biological, radiological, or nuclear attacks.

With such incidents, it is not only possible but also likely that emergency response will involve agencies beyond the local area where the incident occurs. Written agreements to guide such responses and to coordinate local, state, and national resources are now commonplace for wildland firefighting but not yet for antiterrorism or for natural disasters such as floods and hurricanes. This also appears to be a problem area ripe for new OR work.

Refining the Math. There have been numerous published literature surveys on the topic of fire service deployment analysis. The impression one gets from any of these surveys is that most recent work on fire service or ambulance deployment analysis has been limited to mathematical refinements. A new paper describes a model of the same type as one of the older models with some changes in specifications, equations, data sources, or solution methods. There may be one real community that has been used to test the method.

Other issues have kept the market for deployment analysis small and should be priority focuses for any new work: (a) ways to frame deployment analysis so that it is practical, affordable, and useful for small departments and (b) modifications to deployment analysis models to incorporate volunteers and/or mutual aid from neighboring departments [18].

The Future of Deployment Analysis Using Operations Research

Green and Kolesar said that further progress in deployment analysis would depend on better success in finding client organizations that “can act as full-fledged partners,” in establishing projects that encompass multiple agencies and even multiple regions, and

in adapting models and showing validity for extreme events, such as the 9/11 attacks [4].

Given the success of CFAI in establishing a detailed protocol for fire department accreditation—and the interest of fire departments in obtaining the status and benefits associated with accreditation—it would seem prudent for OR professionals to seek to align their models and methods with the CFAI protocol. This seems a promising way to obtain better motivated clients and to reduce resistance from potential clients based on a likely greater allegiance to and comfort with a different approach to such analysis.

FLUID MODELS OF QUEUEING NETWORKS

DAVID GAMARNIK
Operations Research Center and
Sloan School of Management,
MIT, Cambridge, Massachusetts

INTRODUCTION

Fluid models are a powerful approximation technique for studying important dynamic properties of queueing networks. The model is typically derived from an underlying queueing system by replacing a stochastic discrete model with a continuous deterministic model, using a certain law of large numbers type of rescaling. The obtained process reveals a lot fundamental dynamic structures in the underlying system. Historically, the fluid models have been derived in order to analyze the stability (positive recurrence) properties of an underlying queueing system. But since their inception, the technique proved to be useful for other applications such as designing optimal control policies, as well as for the analysis of queueing systems in the heavy traffic regime.

This article introduces basics of fluid models and illustrates them with a lot of examples. We begin with an informal construction to be followed by rigorous definitions and basic properties. A particular focus is given to the notions of stability of fluid models and methods of stability analysis such as the Lyapunov function technique. Examples of stable fluid models are given as well as some counterexamples, illustrating subtle issues in stability analysis. The formality of connections between fluid models and underlying stochastic queueing systems is discussed at a very high level, since the underlying techniques are highly involved and fall outside of the scope of the article. Instead, we point the reader to a rich literature on this subject.

The remainder of the article is organized as follows. A stochastic multiclass queueing

network (MQNET) is defined in the section titled “Multiclass Queueing Network: Model Formulation.” This model serves as the main motivation for introducing and studying the main object of this article—fluid model of an MQNET. Fluid MQNET is introduced informally in the section titled “Informal Derivation of Fluid Equations” using a couple of simple queueing models. Formally, the model is described in the section titled “A Fluid Model of a Multiclass Queueing Network.” Stability of fluid models is discussed in the section titled “Stability of a Fluid Model.” Some basic stability results are established in this section. Lyapunov method of stability analysis is introduced in the section titled “Lyapunov Function Method.” The connections between stability of fluid models and stability of an MQNET are discussed in the section titled “Connections with Stability of Stochastic Queueing Networks.” Apart from this section, all the other sections contain a sufficient amount of technical details and some (simple) proofs. Discussing results in the section titled “Connections with Stability of Stochastic Queueing Networks” in detail would require introduction of sophisticated measure-theoretic notions such as positive Harris recurrence, which falls outside of the scope of this article. Thus instead we give a somewhat informal summary of the main results in this area. The Final section provides notes and sources for material discussed in this article.

Let us introduce some notational conventions. $\mathbb{R}(\mathbb{R}_+)$ denotes the set of (nonnegative) real values. $\mathbb{R}^N$ is the N -dimensional Euclidian space and $\mathbb{R}_+^N$ is the nonnegative quadrant in this space—space of vectors with nonnegative components. Given a matrix $\mathbf{A}$, $\mathbf{A}'$ denotes its transpose. All vectors are assumed to be column vectors. $\mathbf{e}'$ denotes the (row) vector of ones. $\mathbf{I}$ denotes the indicator function. In other words, $\mathbf{I}\{A\}$ equals one if the event A holds true, and equals zero otherwise.

We use without defining some basic objects in queueing theory such as M/M/1 and G/G/1

queueing systems (refer to Kleinrock [1], or any other introductory text on queueing models). The latter is sometimes denoted by GI/GI/1 in order to stress the stochastic independence of interarrival and service times. We simply write it as G/G/1, since in the framework of fluid models only the first order parameters such as arrival rates and service rates play a role. In all of our queueing models no reneging is assumed and all the buffers are assumed to have infinite capacity.

MULTICLASS QUEUEING NETWORK: MODEL FORMULATION

We now introduce the MQNET model. One of earliest and important motivation for this model is wafer fabrication lines [2] and [3]. We introduce the model at a sufficient level of detail in order to facilitate the discussion of fluid models, but some details are omitted in the interest of space. The network consists of J single-server stations $s(1), \dots, s(J)$ and N job classes $1, \dots, N$. Each class $i = 1, \dots, N$ is associated with a unique buffer where the jobs associated with this class are queued. For convenience this buffer is also denoted by i and each buffer is associated with a unique server. The association is described by a $J \times N$ matrix $\mathbf{C} = (C_{ji}, 1 \leq j \leq J, 1 \leq i \leq N)$ with 0–1 entries, where $C_{ji} = 1$ if class i is associated with server $s(j)$ and $C_{ji} = 0$ otherwise.

Classes $i = 1, \dots, N$ are associated with external arrival processes $(A_i(t), t \geq 0)$ and service processes $(S_i(t), t \geq 0)$. For every real value $t \geq 0$, $A_i(t)$ denotes the total number of external arrivals into this class until time t , and $S_i(t)$ denotes the total number of service completions of the class i jobs that the associated server is capable of achieving during the time interval $[0, t]$. In practice, the actual number is typically lower if the server did not have jobs to work on or was working on jobs in a different class. A common assumption is to assume that $A_i(t), S_i(t)$ are renewal processes arising from random i.i.d. interarrival times. Let α_i represent the external arrival rate of the jobs in class i . We understand it in the sense that $\mathbb{E}[A_i(t)] = \alpha_i t + o(t)$ as $t \rightarrow \infty$. Similarly μ_i denotes the service

rate associated with class i . Let $\mathbf{M}$ denote the diagonal $N \times N$ matrix with μ_i in the i th place.

Upon service completion some of the jobs are rerouted to the same or different buffer and the jobs in the same buffer represent the mixture of external and internal arrivals. The routing is given by an $N \times N$ substochastic matrix $\mathbf{P} = (P_{ik} \geq 0, 1 \leq i, k \leq N)$ with the spectral radius strictly less than unity. In other words, $\sum_k P_{ik} \leq 1$ for each i and $\mathbf{P}^n \rightarrow 0$ coordinate-wise as $n \rightarrow \infty$. The second condition is equivalent to saying that every job *eventually* leaves the network (exercise). Here P_{ik} represents the probability that a job which has finished a service in class i is routed to class k . Upon arrival into buffer k the job occupies the last position in the queue. It is assumed that all the routing decisions are made independently for all the jobs. An important special case is when $P_{ik} = 0, 1$, which corresponds to the deterministic routing mechanism. In this case, each row contains at most one entry 1 with column indicating the destination class of the job from class i . When all the entries in a row are zero, the job leaves the network upon the service completion. The parameters $\alpha, \mu, \mathbf{P}, \mathbf{C}$ constitute the basic first order parameters of an MQNET and we write $(\alpha, \mu, \mathbf{P}, \mathbf{C})$ to denote an MQNET.

An important role is played by the load factors which we introduce now. Consider a system of traffic equations in variables $\lambda_i, 1 \leq i \leq N$ given by $\lambda_i = \alpha_i + \sum_{k=1}^N \lambda_k P_{ki}$. In vector form, we have for the (column) vector $\lambda = (\lambda_i, 1 \leq i \leq N)$

$$\lambda = \alpha + \mathbf{P}'\lambda, \quad (1)$$

which admits a unique solution explicitly given as

$$\lambda = [\mathbf{I} - \mathbf{P}']^{-1}\alpha. \quad (2)$$

Intuitively, λ_i represents the total (external plus internal) arrival rate into the buffer i . For every class i and server $s(j)$, define $\rho_i = \lambda_i / \mu_i$ to be the traffic intensity associated with the class i and define $\rho_{s(j)} = \sum_{i \in s(j)} \rho_i$ to be the traffic intensity of the server $s(j)$. Let

Figure 1. An example of an unstable queueing network satisfying Equation (18).

also $\rho = (\rho_i, 1 \leq i \leq N)$. Then

$$\rho = M^{-1}\lambda = M^{-1}[I - P']^{-1}\alpha.$$

Let us illustrate our discussion with an example. Consider the networks depicted in Fig. 1. This is an MQNET with

$$C = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix},$$

$$P = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

No external arrivals are associated with classes 2, 3, and 4. Suppose the arrival rate for the class 1 is $\alpha_1 = 1$. Suppose the service rates are $\mu_1 = \mu_3 = 10, \mu_2 = \mu_4 = 5/3$. The traffic equations (1) and (2) are solved easily to give $\lambda_i = 1, i = 1, 2, 3, 4$. This is consistent with the intuition: class 1 admits only external arrival streams with rate 1. Classes 2, 3, and 4 admit only internal arrival streams, all with rate 1. We also find that $\rho = (1/10, 3/5, 1/10, 3/5)'$, and $\rho_{s(1)} = \rho_{s(2)} = 7/10$.

Another example is described in Fig. 2. The parameters of the network are as follows:

$$N = 3, J = 2, \alpha = (\alpha_1, 0, \alpha_3), \mu = (\mu_1, \mu_2, \mu_3)$$

$$P = \begin{pmatrix} 0 & p & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad C = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}. \quad (3)$$

We obtain $\rho_1 = \alpha_1/\mu_1, \rho_2 = \alpha_1 p/\mu_2, \rho_3 = \alpha_3/\mu_3$.

An important aspect of an MQNET is scheduling policy specification. Given a choice of several jobs how does the server decide which job to work on or when to idle? In this article, we consider a broad class of policy for which we require only two assumptions: (i) the jobs within each class are selected using the first-in-first-out (FIFO) rule (this property is sometimes called *head-of-the-line* type policy), and (ii) scheduling policy is work conserving, namely, servers never idle when they have at least one job waiting to be processed on a server. Most of the scheduling policies considered in the queueing literature, such as FIFO, processor sharing, and static buffer priority (which we simply call a priority policy), satisfy these two properties. We refer to Bramson [4], Dai [5], and Dai and Weiss [6] for definitions and properties of these policies in the stochastic MQNET setting.

Figure 2. A two-server network with three classes.

INFORMAL DERIVATION OF FLUID EQUATIONS

Let us begin by constructing a fluid model of a $G/G/1$ type queueing system, arguing very informally. We begin with a “birds-eye” view of this queueing system in order to intuit the dynamics of this system at large timescales when viewed from a “large distance.”

Fluid Model of a $G/G/1$ Queueing System: “Birds-Eye” View of Stochasticity

Consider a $G/G/1$ queueing system which has a very large number of jobs $Q(0) = n$ at time $t = 0$. Let the arrival rate and service rate of our queueing system be α and μ , respectively. Imagine that you observe this system from a very large distance such that, for example, the difference between queue length 100 and 102 is blurred. Imagine also that you also observe this system for a long time period comparable with n . What do you expect to see?

Consider the initial time interval $[0, nt]$ where $t > 0$ is fixed to be a constant and n grows to infinity. From our assumption $\mathbb{E}[A(t)] = \alpha t + o(t)$, you expect approximately αnt new jobs arriving into the system during this time period. By the same token, the server is capable of serving roughly μnt jobs. When t is sufficiently small, specifically $t < 1/\mu$, this number is smaller than n , and we do not expect a shortage of jobs during this time period, so the server is working all the time during the time interval $[0, t]$. Thus, roughly speaking, we have $Q(nt) \approx n + \alpha nt - \mu nt$ jobs in the system at the end of this period. Another way to write this approximation is

$$\frac{Q(nt)}{n} \approx 1 + \alpha t - \mu t,$$

which is n free in the right-hand side. In order to make the left-hand side also n free, introduce $\bar{Q}(t) = Q(nt)/n$ and rewrite the equation as our first fluid equation: $\bar{Q}(t) \approx 1 + \alpha t - \mu t$. Anticipating that in fact all the approximations $\approx$ can be justified rigorously, we replace it by equality from now on.

What happens for larger t ? The answer depends on the relative magnitude of α and

μ , namely, whether $\rho = \alpha/\mu$ satisfies $\rho > 1$, $\rho = 1$, or $\rho < 1$.

- $\rho > 1$. In this case the arrival rate is faster than the service rate. We expect that the server never runs out of jobs and the fluid equation becomes $Q(nt) \approx n + \alpha nt - \mu nt$, that is,

$$\bar{Q}(t) = 1 + \alpha t - \mu t, \forall t \geq 0.$$

Specifically $\bar{Q}(t)$ diverges to infinity at a linear rate $\alpha - \mu > 0$.

- $\rho = 1$. In this case, our reasoning suggests again that the server never runs out of jobs, but since $\alpha = \mu$, we simply obtain $Q(nt) \approx n + \alpha nt - \mu nt = n$, that is,

$$\bar{Q}(t) = 1, \forall t \geq 0. \quad (4)$$

A way to reason and justify this is to observe that $Q(t)$ is a symmetric random walk constrained to stay on nonnegative integers. Starting from state $Q(0) = n$ during time interval $[0, nt]$ it fluctuates at the level $O(\sqrt{nt})$ (in fact the fluctuation becomes a driftless Brownian motion). This correction $O(\sqrt{nt})$ is washed away on the fluid n -scale, and we obtain the limiting equation (4).

- $\rho < 1$. This is the most interesting case. Since $\alpha < \mu$, the total number of jobs steadily decreases until the server empties for the first time. The fluid equation is again $Q(nt) \approx n + \alpha nt - \mu nt$, but it is valid only until the first emptying time which we expect to happen around time $n/(\mu - \alpha)$. After this, we expect the system to have usual steady-state type fluctuations that do not depend on n —the initial queue length. In other words, $Q(nt)/n \approx 0$. We conclude

$$\bar{Q}(t) = \begin{cases} 1 + \alpha t - \mu t, & t \leq \frac{1}{\mu - \alpha}; \\ 0, & t > \frac{1}{\mu - \alpha}. \end{cases} \quad (5)$$

We can summarize all three cases by writing $\bar{Q}(t) = \max(1 + \alpha t - \mu t, 0)$. If we begin with nx , many jobs at time zero, instead of n , but still keep n as our scaling parameter,

we obtain $\bar{Q}(t) = \max(x + \alpha t - \mu t, 0)$. Yet, another way to write the fluid equation (5), for the interesting case $\rho < 1$ is $\bar{Q}(t) = x + \alpha t - \mu T(t)$, where $T(t) = t$ for $t \leq x/(\mu - \alpha)$ and $T(t) = x/(\mu - \alpha) + \rho t$ otherwise (check the validity of this). There is a good physical interpretation of the function $T(t)$ —it is the scaled cumulative amount of time that the server was working. Up until time $x/(\mu - \alpha)$ the queue was positive and the server was working full time, thus giving $T(t) = t$. After this time, the system is more or less in steady state, where we know from Little's Law, the average time that the server is busy is ρ . Hence the expression for T after the critical time $x/(\mu - \alpha)$.

More General Constructs: Many Classes, Scheduling Policies, Routing

How can we generalize our informal derivations of a fluid model to more general and interesting cases, for example, networks of queues with many classes such as MQNET described in the previous section?

Consider a multiclass single-server ($J = 1$) queueing system with classes $i = 1, 2, \dots, N$. For simplicity, let us assume that there is no feedback in the system. In other words, all the jobs leave the system after their first service completion. Using the terminology of the previous section, we consider $(\alpha, \mu, \mathbf{P})$ with $\mathbf{P} = 0$. Suppose we begin with $nx_i, x_i > 0$ jobs in class $i = 1, 2, \dots, N$, where n is again very large. We focus first on the workload at time t , defined for a moment as $W(t) = \sum_{1 \leq i \leq N} Q_i(t)/\mu_i$. The workload changes at the rate approximately $\sum_i \alpha_i/\mu_i - 1 = \rho - 1$ per unit of time. Specifically, if $\rho < 1$, we expect it to hit zero for the first time around time t_0 satisfying $\sum_i nx_i + (\rho - 1)t_0 = 0$, namely, $t_0 = \sum_i nx_i/(1 - \rho)$. After this moment, just as in the $G/G/1$ case, the system experiences the steady-state type stochastic fluctuations which are n independent. Thus, we expect the following fluid equation for the fluid model of a workload process $\bar{W}(t) \triangleq W(nt)/n$

$$\bar{W}(t) = \begin{cases} \sum_i \frac{x_i}{\mu_i} + (\rho - 1)t, & t \leq t_0; \\ 0, & t > t_0. \end{cases} \quad (6)$$

What about the individual queues $Q_i(t)$? Naturally, their dynamics depend on the choice of the scheduling policy. Yet, without specifying the policy, we can still say something in the fluid equations. Let $T_i(t)$ be the total time spent by the server working on class i jobs during the interval $[0, t]$ and let $\bar{T}_i(t) = T_i(nt)/n$. Trivially, $\sum_i T_i(nt) \leq nt$, that is, $\sum_i \bar{T}_i(t) \leq t$. Since during the time interval $[0, nt_0]$, we expect the system to be fully busy, the following relation seems reasonable: $\sum_i \bar{T}_i(t) = t, \forall t \leq t_0$.

We expect roughly $\mu_i T_i(nt)$ type i jobs to be processed during the time interval $[0, nt]$. Also roughly $\alpha_i nt$ jobs arrive during this time interval. We obtain $Q_i(t) = nx_i + \alpha_i nt - \mu_i T_i(nt)$, $t \leq t_0$, which leads to a fluid equation $\bar{Q}_i(t) = x_i + \alpha_i t - \bar{T}_i(t)$, $t \leq t_0$. The following set of fluid equations is then obtained:

$$\bar{Q}_i(t) = \begin{cases} x_i + \alpha_i t - \mu_i \bar{T}_i(t), & \forall t \leq t_0, \\ 0, & \forall t > t_0, \end{cases} \quad 1 \leq i \leq N.$$

$$\sum_{i=1}^N \bar{T}_i(t) = t, \forall t \leq t_0,$$

$$\sum_{i=1}^N \bar{T}_i(t) \leq t, \forall t \geq 0.$$

How do we incorporate scheduling policy into the fluid equations? In fact, we already did it via quantities $\bar{T}_i(t)$ as they encode the relative effort dedicated by the server to each individual class during a given time interval. Sometimes additional conditions on $\bar{T}_i(t)$ are added resulting from details of a policy.

It remains to derive the fluid equation in the presence of feedback and routing, specifically probabilistic routing. Consider the following network in Fig. 2 described in the earlier section. Rather than deriving the full set of fluid equations, let us focus on the second queue $Q_2(t)$. Suppose initially we have $Q_i(0) = nx_i, i = 1, 2$. During the timer interval $[0, nt]$, the first server processes roughly $\mu_1 T_1(nt)$ jobs out of which roughly $\mu_1 T_1(nt)p$ will be routed to the second queue. Also during the same time period roughly $\mu_2 T_2(t)$ jobs will be served in the second server. Thus

we can write the following fluid equation for the second queue: $\bar{Q}_2(t) = x_2 + \mu_1 \bar{T}_1(t)p - \mu_2 \bar{T}_2(t)$, in addition to the already derived equation $\bar{Q}_1(t) = x_1 + \alpha_1 t - \mu_1 \bar{T}_1(t)$.

With this in mind we now turn to a formal definition of fluid models.

A FLUID MODEL OF A MULTICLASS QUEUEING NETWORK

Consider an MQNET $(\alpha, \mu, \mathbf{P}, \mathbf{C})$. The network consists of N classes and J service stations $s(1), \dots, s(J)$.

Definition 1. A fluid model associated with a network $(\alpha, \mu, \mathbf{P}, \mathbf{C})$ is defined to be the set of solutions $\bar{\mathbf{Q}}(t) = (\bar{Q}_1(t), \dots, \bar{Q}_N(t))$, $\bar{\mathbf{T}}(t) = (\bar{T}_1(t), \dots, \bar{T}_N(t))$ to the following system of functional equations and inequalities.

$$\bar{Q}_i(t) = \bar{Q}_i(0) + \alpha_i t + \sum_{j=1}^N \mu_j p_{ji} \bar{T}_j(t) - \mu_i \bar{T}_i(t), \quad (7)$$

$$\sum_{i \in s(j)} \bar{T}_i(t) - \bar{T}_i(s) \leq t - s, \quad (8)$$

$$\bar{T}_i(t) \text{ is nondecreasing, } \bar{T}_i(0) = 0, \text{ and } \bar{Q}_i(t) \geq 0 \quad (9)$$

for all $i = 1, 2, \dots, N, t, s \in \mathbb{R}_+, t \geq s$.

Any solution $(\bar{\mathbf{Q}}(t), \bar{\mathbf{T}}(t))$ to the system of equations 7–9 is called a *fluid solution* to the fluid model. We think of $\bar{\mathbf{Q}}(0)$ as the initial state of a fluid solution. We can rewrite Equation (7) in the matrix form:

$$\bar{\mathbf{Q}}(t) = \bar{\mathbf{Q}}(0) + \alpha t + (\mathbf{P}' - \mathbf{I})\mathbf{M}\bar{\mathbf{T}}(t). \quad (10)$$

From this we immediately obtain that for every $s < t$

$$\bar{\mathbf{Q}}(t) = \bar{\mathbf{Q}}(s) + \alpha(t - s) + (\mathbf{P}' - \mathbf{I})\mathbf{M}(\bar{\mathbf{T}}(t) - \bar{\mathbf{T}}(s)). \quad (11)$$

Thus, for each $s \geq 0$ we obtain a new fluid solution $\bar{\mathbf{Q}}'(t) = \bar{\mathbf{Q}}(t + s)$, $\bar{\mathbf{T}}'(t) = \bar{\mathbf{T}}(t + s) - \bar{\mathbf{T}}(s)$, $t \geq 0$ (check that this is indeed a fluid solution). Multiplying both

sides of Equation (10) by $M^{-1}[\mathbf{I} - \mathbf{P}']^{-1}$, we obtain

$$M^{-1}[\mathbf{I} - \mathbf{P}']^{-1}\bar{\mathbf{Q}}(t) = M^{-1}[\mathbf{I} - \mathbf{P}']^{-1}\bar{\mathbf{Q}}(0) + \rho t - \bar{\mathbf{T}}(t).$$

Define $\bar{\mathbf{Q}}_{s(j)} = \sum_{i \in s(j)} \bar{Q}_i(t)$, $\bar{\mathbf{T}}_{s(j)} = \sum_{i \in s(j)} \bar{T}_i(t)$. For the reasons which will become clear in future, define also $\bar{\mathbf{W}}(t) = (\bar{W}_i(t), 1 \leq i \leq N) \triangleq M^{-1}[\mathbf{I} - \mathbf{P}']^{-1}\bar{\mathbf{Q}}(t) \geq 0$ to be the *fluid workload* of the fluid solution at time t . Observe that $\bar{\mathbf{W}}(t) \neq 0$ if and only if $\bar{\mathbf{Q}}(t) \neq 0$ (show this). Also define $\bar{W}_{s(j)}(t) \triangleq \sum_{i \in s(j)} \bar{W}_i(t)$ to be the *fluid workload* in server $s(j)$ at time t . In terms of these definitions, we obtain

$$\bar{\mathbf{W}}(t) = \bar{\mathbf{W}}(0) + \rho t - \bar{\mathbf{T}}(t), \quad (12)$$

$$\bar{W}_{s(j)}(t) = \bar{W}_{s(j)}(0) + \rho_{s(j)}t - \sum_{i \in s(j)} \bar{T}_i(t), \quad \forall j = 1, \dots, J. \quad (13)$$

Basic Properties of a Fluid Model

What properties should a fluid solution $(\bar{\mathbf{Q}}(t), \bar{\mathbf{T}}(t))$ satisfy? The proof of the following observation is an easy exercise.

Proposition 1. Every fluid solution $(\bar{\mathbf{Q}}(t), \bar{\mathbf{T}}(t))$ is Lipschits continuous.

Looking at the fluid solution $\bar{\mathbf{Q}}(t) = \max(\bar{\mathbf{Q}}(0) + \alpha t - \mu t, 0)$ we see that the solution while continuous is not necessarily differentiable. This turns out not to be a major problem. The following fact is known from real analysis: for every Lipschits continuous function f there exists a set $A \subset \mathbb{R}$ such that for every $t \in A$, $\dot{f}(t)$ exists and $\mathbb{R} \setminus A$ has Lebesgue measure zero [7]. In other words, while the derivative does not exist everywhere, it exists *almost* everywhere, in the measure-theoretic sense. Throughout this article, we consider derivatives at various time instances implicitly assuming that we consider only times when derivatives exist. In light of Proposition 1, the derivatives of $\bar{\mathbf{Q}}(t)$ and $\bar{\mathbf{T}}(t)$ exist almost everywhere. Using a simplifying notation $\mathbf{u}(t) = d\bar{\mathbf{T}}(t)/dt$,

we obtain from Equations (10), (8) and (9), respectively,

$$\frac{d\bar{Q}(t)}{dt} = \alpha + [\mathbf{P}' - \mathbf{I}]\mathbf{M}\mathbf{u}(t), \quad (14)$$

$$\sum_{i \in s(j)} u_i(t) \leq 1, \forall j = 1, \dots, J, \quad (15)$$

$$\mathbf{u}(t) \geq 0. \quad (16)$$

Let $u_{s(j)}(t) \triangleq \sum_{i \in s(j)} u_i(t)$. Informally, $u_{s(j)}(t)$ represents the *rate* at which server $s(j)$ works at time t . The amount of time that the server $s(j)$ was idling during some time period $[t_1, t_2]$ can be measured in terms of fluid solution as $t_2 - t_1 - \sum_{i \in s(j)} (\bar{T}_i(t_2) - \bar{T}_i(t_1))$. It thus makes sense to define a fluid solution to be work conserving if the amount of idling is zero whenever the fluid level in the server is positive.

Definition 2. A fluid solution $(\bar{Q}(t), \bar{T}(t))$ is defined to be *work conserving* or *non-idling* if for every server $s(j)$ and every $t_1 < t_2$

$$\inf_{t_1 \leq s \leq t_2} \sum_{i \in s(j)} \bar{Q}_i(s) > 0,$$

we have

$$\sum_{i \in s(j)} (\bar{T}_i(t_2) - \bar{T}_i(t_1)) = t_2 - t_1.$$

Examples of Fluid Models and Fluid Solutions

Given a fluid model, does it have at least one fluid solution? The answer is trivially yes: set $\bar{T}(t) = 0$ for all t and $\bar{Q}(t) = \bar{Q}(0) + \alpha t$. Check that this is indeed a fluid solution. But it is not a very interesting one. It essentially corresponds to the case when all servers are idling all the time and, as a result, the queues are building up at a linear rate. A more interesting case is existence of at least one work-conserving fluid solution. The answer is again positive but this is harder to prove and we leave it as an exercise. Let us now turn to specific examples of fluid model.

G/G/1 Queueing System. We assume $\rho < 1$. For this and the following examples let us focus exclusively on work-conserving fluid solutions. We seek solutions to the system of equations and inequalities:

$$\bar{Q}(t) = \bar{Q}(0) + \alpha t - \mu \bar{T}(t),$$

$$\bar{T}(t) - \bar{T}(s) \leq t - s, \forall s < t,$$

Satisfying, in addition, the work-conservation requirement and $\bar{T}(0) = 0$. Observe that $\bar{T}(t) \leq t$ inequality implies that $\bar{Q}(t) \geq \bar{Q}(0) + \alpha t - \mu t > 0$ for all $t < \tau \triangleq \bar{Q}(0)/(\mu - \alpha)$. The work-conservation condition then implies $\bar{T}(t) = t$ for all $t < \tau$. As a result, we must have $\bar{Q}(t) = \bar{Q}(0) + \alpha t - \mu t$ for all such $t < \tau$. The continuity of the fluid solution implies that $\bar{Q}(\tau) = \bar{Q}(0) + \alpha \tau - \mu \tau = 0$. We have established the existence and uniqueness of the fluid solution at least on the interval $[0, \tau]$. What happens next? It is easy to check that $\bar{Q}(t) = 0, \bar{T}(t) = \tau + \rho(t - \tau)$ for $t \geq \tau$ is a fluid work-conserving solution (recall that we already informally derived this). Let us now show that it is in fact unique. Suppose there exists a solution $(\bar{Q}(t), \bar{T}(t))$ such that $\bar{Q}(t') \neq 0$ for some $t' > \tau$. By continuity of $\bar{Q}(t)$ we have that the set $\{t : \bar{Q}(t) \neq 0\}$ is an open subset of $[0, \infty)$. A theorem from real analysis [7] states that every open subset of a real line can be represented as a finite or countable union of non-overlapping open intervals $\cup_i (a_i, b_i)$. Thus t' must fall into one of those intervals, say (a_k, b_k) . Notice that $\tau \leq a_k$ (why?). By work conservation we have $\bar{T}(s) - \bar{T}(a_k) = s - a_k$ for all $s \in (a_k, b_k)$. We have $\bar{Q}(a_k) = 0$ and then from Equation (11) we obtain

$$\begin{aligned} \bar{Q}(t') &= \bar{Q}(a_k) + \alpha(t' - a_k) - \mu(t' - a_k) \\ &= \alpha(t' - a_k) - \mu(t' - a_k) \\ &< 0, \end{aligned}$$

since $\rho < 1$, but this is a contradiction. We conclude that the unique work-conserving fluid solution is

$$\bar{Q}(t) = \max(0, \bar{Q}(0) + \alpha t - \mu t),$$

$$\bar{T}(t) = \mathbf{1}\{t \leq \tau\}t + \mathbf{1}\{t > \tau\}(\tau + \rho(t - \tau)),$$

where $\tau = \bar{Q}(0)/(\mu - \alpha)$.

Characterizing fluid solutions explicitly for more complicated networks would be a daunting task. Instead, we are content with getting an insight into the *qualitative* behavior of fluid models. This becomes particularly important when we turn to the issues of stability of fluid models.

STABILITY OF A FLUID MODEL

We now turn to the important property—stability of a fluid model and its relationship to the stability of underlying queueing systems. From basic queueing theory we know that $G/G/1$ queue is stable if and only if $\rho < 1$. On the other hand, as we have seen, $\rho < 1$ is precisely the condition under which the unique work-conserving fluid solution of a $G/G/1$ queueing system converges to zero and stays at zero after some initial time. This is not a coincidence. We can think of $G/G/1$ being stable under the $\rho < 1$ condition as the property that *no matter how large* was the initial number of jobs in the queue, this large backlog will be cleared at some point and the system will enter the steady-state regime.

Definition 3. A fluid solution $(\bar{\mathbf{Q}}(t), \bar{\mathbf{T}}(t))$ is defined to be stable if there exists $\tau > 0$ such that $\bar{\mathbf{Q}}(t) = 0, \forall t \geq \tau$. A fluid model $(\alpha, \mu, \mathbf{P}, \mathbf{C})$ is defined to be globally stable if every work-conserving fluid solution is stable.

The word global is used in the definition to indicate the property of the network itself rather than the property of a particular fluid solution. The emptying time τ per our definition is solution specific, even though we see that in many interesting cases there exists one τ that works for *all* fluid solutions.

Observe that if the fluid solution $\bar{\mathbf{Q}}(t)$ becomes zero after time τ , then from Equation (10) we obtain

$$0 = \frac{d\bar{\mathbf{Q}}(t)}{dt} = \alpha + (\mathbf{P}' - \mathbf{I})\mathbf{M}\mathbf{u}(t), \quad (17)$$

namely, $\mathbf{u}(t) = \mathbf{M}^{-1}[\mathbf{I} - \mathbf{P}']^{-1}\alpha = \rho$. In other words, $\bar{\mathbf{T}}(t) = \bar{\mathbf{T}}(\tau) + \rho t$ for all $t \geq \tau$. We can interpret this observation as servers working just enough time to prevent fluid from building up from level zero.

Let us establish some preliminary results on stability. Our first result connects stability with the traffic intensity parameter ρ .

Theorem 1. *A necessary condition for a global stability is*

$$\rho_{s(j)} < 1 \quad (18)$$

for every $j = 1, \dots, J$.

Proof. Suppose the traffic intensity of some server $s(j)$ satisfies $\rho_{s(j)} \geq 1$. We have from Equations (13) and (8)

$$\begin{aligned} \bar{W}_{s(j)}(t) &= \bar{W}_{s(j)}(0) + \rho_{s(j)}t - \sum_{i \in s(j)} \bar{T}_i(t) \\ &\geq \bar{W}_{s(j)}(0) + \rho_{s(j)}t - t \\ &\geq \bar{W}_{s(j)}(0). \end{aligned}$$

Thus it suffices to exhibit a starting point $\bar{\mathbf{Q}}(0)$ such that $\bar{W}_{s(j)}(0) > 0$. Letting $\mathbf{C}_j$ denote the j th row of $\mathbf{C}$, we have

$$\begin{aligned} \bar{W}_{s(j)}(0) &= \mathbf{C}'_j \bar{\mathbf{W}}(0) \\ &= \mathbf{C}'_j \mathbf{M}^{-1}[\mathbf{I} - \mathbf{P}']^{-1} \bar{\mathbf{Q}}(0) \\ &= \mathbf{C}'_j \mathbf{M}^{-1} \left(\mathbf{I} + \sum_{m \geq 1} (\mathbf{P}')^m \right) \bar{\mathbf{Q}}(0) \\ &\geq \mathbf{C}'_j \mathbf{M}^{-1} \bar{\mathbf{Q}}(0) \\ &= \sum_{i \in s(j)} \mu_i^{-1} \bar{Q}_i(0). \end{aligned}$$

Thus every fluid solution with a starting point $\bar{\mathbf{Q}}(0)$ satisfying $\bar{Q}_{s(j)} > 0$ never reaches zero.

Thus, from now on we focus on the case when Equation (18) holds. Next we establish that this condition is also sufficient in the case of a single-server queueing system.

Theorem 2. *A single-server ($J = 1$) fluid model $(\alpha, \mu, \mathbf{P})$ is globally stable if and only if $\rho < 1$.*

Proof. Using Theorem 1, it suffices to assume $\rho < 1$. From Equation (13), we have that

the workload $\bar{W}(t)$ of our unique server satisfies

$$\bar{W}(t) = \bar{W}(0) + \rho t - \sum_i \bar{T}_i(t). \quad (19)$$

Owing to constraint (8), we have $\bar{W}(t) > 0$ for all $t \leq \tau \triangleq \bar{W}(0)/(1 - \rho)$, which implies $\bar{Q}(t) \neq 0, \forall t < \tau$, which further implies that $\sum_i \bar{T}_i(t) = t, \forall t < \tau$, by work conservation. It then follows that $\bar{W}(\tau) = \bar{W}(0) + \rho\tau - \tau = 0$, implying $\bar{Q}(\tau) = 0$, and we established that every work-conserving fluid solution reaches zero exactly at time τ . We claim further that $\bar{Q}(t) = 0, \forall t > \tau$, and the proof of this is a generalization of an argument already used in the special case of a fluid model corresponding to a $G/G/1$ queueing system. We leave it to the reader to complete the argument.

Unstable Fluid Model

The stability property would be simple if the traffic intensity condition (18) was also sufficient for stability. However, this is, unfortunately, not the case. We now present an example of a network such that Equation (18) is satisfied, yet an unstable fluid solution exists. Consider the two-server four classes network depicted in Fig. 1. We assume $\alpha = (\alpha, 0, 0, 0), \mathbf{P}_{ii+1} = 1, i = 1, 2, 3, P_{ij} = 0$ for all other j , otherwise; $\mathbf{C}_{11} = \mathbf{C}_{14} = \mathbf{C}_{22} = \mathbf{C}_{23} = 1, \mathbf{C}_{ij} = 0$ otherwise. This network is called *Lu-Kumar network* due to authors [8] who introduced this network. A similar phenomenon was introduced for the first time in a related work by Kumar and Seidman [9].

Theorem 3. *The Lu-Kumar network depicted in Fig. 1 is unstable if $\rho_2 + \rho_4 \geq 1$.*

The proof of this result is involved, but conceptually not complicated. The idea is to build a concrete solution satisfying the required properties. It leads to an alternating cycle behavior where a large amount of fluid is accumulated at either first or second server at different times. This behavior induces a starvation where a server nominally capable of processing jobs waits for these jobs for too long (“starves”).

Feedforward Fluid Models are Stable

As we said before, the reason that an unstable fluid solution exists in the network depicted in Fig. 1 has to do with the property that the two servers alternate in “starvation,” thus creating an increasing backlog of work. This was possible due to a mutual feedback existing between the two servers. It turns out that this feedback is necessary for the nontrivial mode of instability (i.e., instability in underloaded networks) to take place. We now show that if the feedback in the network is one sided and the network is underloaded, then it is also stable.

A fluid network $(\alpha, \mu, \mathbf{P}, \mathbf{C})$ is called *feedforward* or *acyclic* if for every $1 \leq j_1 < j_2 \leq J$, and every $i \in s(j_1), l \in s(j_2)$, we must have $p_{li} = 0$. In other words, jobs go through the servers in a nondecreasing order. A simple example of such a network is a tandem queueing network consisting of J servers. Another example is the network in Fig. 2.

Theorem 4. *A feedforward fluid network is stable if condition (18) is met.*

The proof is based on a certain induction argument. One can show that for every j , the server $s(j)$ and all the servers preceding it become empty at a certain time t_j , and the outflow from these servers becomes equal to the inflows. In other words, these servers practically “disappear” from the network. Each successive server can be analyzed as a single-server fluid MQNET.

LYAPUNOV FUNCTION METHOD

Now that we realize that stability is indeed a nontrivial property and is not simply captured by the load condition (18), it would be useful to have general methods that can help us to determine at least sufficient conditions for stability. Unfortunately, as we discuss in the last section, one cannot hope for establishing stability property exactly for every given network. However, for practical applications perhaps we can identify some methods that provide *sufficient* if not always *necessary* conditions for stability. One of such

most powerful methods is the Lyapunov function method, which draws from a general theory of differential equations and dynamical systems.

Definition 4. A function $\Phi : \mathbb{R}^N \rightarrow \mathbb{R}_+$ is called a Lyapunov function if $\Phi(x) = 0$ if and only if $x = 0$ and there exists $\gamma > 0$ such that for every time interval (t_1, t_2) and every fluid solution satisfying $\bar{Q}(t) \neq 0, \forall t \in (t_1, t_2)$, we have

$$\Phi(\bar{Q}(t_2)) - \Phi(\bar{Q}(t_1)) \leq -\gamma(t_2 - t_1).$$

If Lyapunov function Φ is differentiable, then, using the chain differentiation rule, the condition can be restated equivalently as

$$\nabla \Phi \cdot \frac{d\bar{Q}(t)}{dt} \leq -\gamma,$$

for all t where $\bar{Q}(t) \neq 0$ and the derivative of $\bar{Q}(t)$ is defined. Here, $\nabla \Phi$ denotes the gradient of Φ .

The idea behind the Lyapunov function construction is to find a certain function (sometimes also called *potential*) of the state space which decreases with time as long as the state $\bar{Q}(t)$ is nonzero. The trick is to turn a multidimensional process $\bar{Q}(t)$ into a one-dimensional process $\Phi(\bar{Q}(t))$.

Let us now show that Lyapunov functions are useful because they provide sufficient conditions for stability.

Theorem 5. *Given a fluid network (α, μ, P, C) suppose a Lyapunov function Φ exists. Then the network is globally stable.*

Proof. Fix any $\tau > \Phi(\bar{Q}(0))/\gamma$. If $\bar{Q}(t) \neq 0$ for all $0 \leq t \leq \tau$, then $\Phi(\bar{Q}(\tau)) \leq \Phi(\bar{Q}(0)) - \gamma\tau < 0$ —contradiction. Thus $\bar{Q}(t_0) = 0$ for some $t_0 \leq \Phi(\bar{Q}(0))/\gamma$. Suppose $\bar{Q}(t) \neq 0$ for some $t > t_0$. In this case, $t_1 = \inf\{t \geq t_0 : \bar{Q}(t) \neq 0\}$ is finite. Then, by continuity, we can find that $t_2 > t_1 \geq t_0$ such that $\bar{Q}(t_1) = 0$ and $\bar{Q}(t) \neq 0$ for all $t \in (t_1, t_2]$. But then $\Phi(\bar{Q}(t_2)) \leq \Phi(\bar{Q}(t_1)) - \gamma(t_2 - t_1) = -\gamma(t_2 - t_1) < 0$ —contradiction again. We conclude, $\bar{Q}(t) = 0, \forall t \geq t_0$.

Let us now demonstrate Lyapunov function method with some examples.

Multiclass Single-Server Queueing System.

Recall (Theorem 2) that such a system is stable provided $\rho < 1$. In fact our proof is essentially based on constructing a Lyapunov function. Let $\Phi(x) = e'M^{-1}[I - P]^{-1}x$. Check that Φ is zero only at $x = 0$. Then $\Phi(\bar{Q}(t))$ is simply the workload $\bar{W}(t)$ of the server for which we have a fluid equation (19). Whenever $\bar{Q}(t) \neq 0$ over some interval, (t_1, t_2) we have $\sum_i (\bar{T}_i(t_2) - \bar{T}_i(t_1)) = t_2 - t_1$, implying

$$\bar{W}(t_2) - \bar{W}(t_1) \leq (\rho - 1)(t_2 - t_1).$$

Thus, the linear function Φ is indeed a Lyapunov function with $\gamma = 1 - \rho$.

Let us consider more sophisticated applications of the Lyapunov function method to the question of stability of fluid models. Our first example is generalized Jackson network (GJN) considered in the section titled “Multiclass Queueing Network: Model Formulation”. For simplicity, we call this model fluid Jackson network and denote it by (α, μ, P) . An interesting and deep result is that fluid Jackson network is always stable under the usual load conditions. In other words, the instability can only be caused by multiplicity of classes in the network.

Theorem 6. *A fluid Jackson network (α, μ, P) is globally stable provided the load condition (18) holds.*

The proof is based on showing that $\Phi(x) = e'M^{-1}[I - P]^{-1}x$ is a linear Lyapunov function [5] and [10]. It can be shown that a fluid Jackson network has, in fact, a unique non-idling solution for every starting state $Q(0)$. Thus, global stability in this case is equivalent to just stability.

For another demonstration of the power of the Lyapunov function method, let us return to the Lu–Kumar network depicted in Fig. 1. Recall Theorem 3 stating that this network can be unstable under the assumption $\rho_2 + \rho_4 \geq 1$. It turns out that this is the necessary condition for the existence of an unstable trajectory, in addition, of course, to Equation (18). The result below then gives us a complete global stability picture for this network.

Theorem 7. *The Lu-Kumar network is globally stable if and only if the load condition (18) holds and $\rho_2 + \rho_4 < 1$.*

Proof. In light of Theorem 3, it suffices to consider the case $\rho_2 + \rho_4 < 1$. We construct an appropriate Lyapunov function. It turns out that the following choice works (though it is not obvious yet why). Let

$$\theta_1 = 1 - \rho_4 - \min \left((1 - \rho_1 - \rho_4)/2, \right. \\ \left. \times (1 - \rho_2 - \rho_4)/3 \right) \quad (20)$$

$$\theta_2 = \rho_2 + \min \left((1 - \rho_2 - \rho_3)/2, \right. \\ \left. \times (1 - \rho_2 - \rho_4)/3 \right). \quad (21)$$

For every $x = (x_1, \dots, x_4) \in \mathbb{R}_+^4$, let

$$\Phi_1(x) = \theta_1 x_1 + (1 - \theta_1) \sum_{1 \leq i \leq 4} x_i, \\ \Phi_2(x) = \theta_2(x_1 + x_2) + (1 - \theta_2)(x_1 + x_2 + x_3).$$

Now define the Lyapunov function Φ as $\Phi(x) = \max(\Phi_1(x), \Phi_2(x))$. Observe that $\Phi(x)$ is a Lipschitz continuous function. Thus $\Phi(\bar{Q}(t))$ has derivatives for almost all t , along with $\bar{Q}_i(t), \bar{T}_i(t)$. Given such t , let $\mathcal{I} = \mathcal{I}(t) \subset \{1, 2\}$ such that $\Phi_i(\bar{Q}(t)) = \Phi(\bar{Q}(t))$ for every $i \in \mathcal{I}$ (the only choices are $\mathcal{I} = \{1\}, \{2\}, \{1, 2\}$). The following is left as an exercise:

$$\frac{d\Phi(\bar{Q}(t))}{dt} = \frac{d\Phi_i(\bar{Q}(t))}{dt} \quad (22)$$

for every $i \in \mathcal{I}$.

Now let us show that for each server $s(i), i = 1, 2$, if the total fluid level in this server is nonzero at time t , then $\frac{d\Phi_i(\bar{Q}(t))}{dt} \leq -\gamma$, for some positive γ . Consider server $s(1)$. We have

$$\frac{d\Phi_1(\bar{Q}(t))}{dt} = \theta_1(\alpha - \mu_1 u_1(t)) + (1 - \theta_1) \\ \times (\alpha - \mu_4 u_4(t)) \\ = \alpha - \theta_1 \mu_1 u_1(t) - (1 - \theta_1) \mu_4 u_4(t).$$

Now if $\sum_{i \in s(1)} \bar{Q}_i(t) = \bar{Q}_1(t) + \bar{Q}_4(t) > 0$, then $u_1(t) + u_4(t) = 1$. In light of this the

derivative is indeed negative, provided that $\alpha < \theta_1 \mu_1$ and $\alpha < (1 - \theta_1) \mu_4$. Check that this is indeed the case.

Now consider the server $s(2)$. We have

$$\frac{d\Phi_2(\bar{Q}(t))}{dt} = \theta_2(\alpha - \mu_2 u_1(t)) + (1 - \theta_2) \\ \times (\alpha - \mu_3 u_3(t)) \\ = \alpha - \theta_2 \mu_2 u_2(t) - (1 - \theta_2) \mu_3 u_3(t).$$

Again if $\sum_{i \in s(2)} \bar{Q}_i(t) > 0$, then $u_2(t) + u_3(t) = 1$, and the derivative is negative provided that $\alpha < \theta_2 \mu_2$ and $\alpha < (1 - \theta_2) \mu_3$. Check again that this is indeed the case.

Now we claim that if $\bar{Q}(t) \neq 0$ and $\sum_{i \in s(1)} \bar{Q}_i(t) = 0$, then $\Phi_1(\bar{Q}(t)) \leq \Phi_2(\bar{Q}(t))$, and similarly, if $\sum_{i \in s(2)} \bar{Q}_i(t) = 0$, then $\Phi_2(\bar{Q}(t)) \leq \Phi_1(\bar{Q}(t))$. Let us first see what this claim gives us. In light of Equation (22), this claim provides us with the conclusion that the derivative of $\Phi(\bar{Q}(t))$ equals the derivative of $\Phi_i(\bar{Q}(t)), i = 1, 2$, such that the corresponding server $s(i)$ has a positive amount of fluid. But we just showed that in this case the derivative of $\Phi_i(\bar{Q}(t))$ is negative and the proof of the theorem is complete. Thus, it remains to check the claim. First, suppose $\sum_{i \in s(2)} \bar{Q}_i(t) = 0$. Then,

$$\Phi_2(\bar{Q}(t)) = \bar{Q}_1(t) \leq \bar{Q}_1(t) \\ + (1 - \theta_1) \bar{Q}_4(t) = \Phi_1(\bar{Q}(t)),$$

and the assertion is established.

Now suppose $\sum_{i \in s(1)} \bar{Q}_i(t) = 0$. Then,

$$\Phi_1(\bar{Q}(t)) = (1 - \theta_1)(\bar{Q}_2(t) + \bar{Q}_3(t)), \\ \Phi_2(\bar{Q}(t)) = \bar{Q}_2(t) + (1 - \theta_2) \bar{Q}_3(t).$$

The claim follows since $1 - \theta_1 < 1 - \theta_2$, which is easily checked.

CONNECTIONS WITH STABILITY OF STOCHASTIC QUEUEING NETWORKS

Up until now we have not discussed two important questions. How does the stability property of a fluid model connect with the stability property of a stochastic MQNET, and do we have tools to determine stability of fluid

models exactly, (as opposed to just obtaining sufficient conditions provided, e.g., by constructing a Lyapunov functions)? These are perhaps the two most important questions. Because of the complexity of the underlying techniques involved, we only give a brief and somewhat informal summary of results. The appropriate references can be found in the next section.

The first one has to begin with a formal definition of stability of a queueing network. Intuitively, we say that a queueing network is stable if the queue length does not grow without a bound in some sense, say in expectation, as time goes to infinity. In classical queueing models, such as M/M/N queueing system, the formal definition of stability is positive recurrence of the underlying Markovian process. This notion can be generalized to multiclass queueing networks using the notion of so-called positive Harris recurrence. The Harris recurrence is an appropriate framework to discuss recurrence properties of Markov chains in general (not necessarily countable) state space. It turns out that there indeed exists a very important, albeit one directional, connection between the stability of a fluid model and its stochastic counterpart.

Theorem 8. *Suppose a fluid model is globally stable. Then, the underlying MQNET is positive Harris recurrent for every work-conserving scheduling policy.*

The theorem as stated is not completely precise. In fact, it was stated and proven for a broad class of so-called head-of-the-line type scheduling policies—policies that within each class use the FIFO rule. The notion of scheduling policies in MQNETs requires a special technical discussion on its own which we skip. Unfortunately, the converse result does not necessarily hold.

Theorem 9. *There exists an MQNET and a (priority) scheduling policy such that the corresponding fluid solution is unstable, yet the network is positive Harris recurrent.*

A similar result is known also for the FIFO policy. Again care is needed in order to properly define the “corresponding” fluid solution.

Sometimes this is defined as a weak limit of stochastic MQNET processes under the law of large numbers type of rescaling. In general, this weak limit is sometimes called *fluid limit* as opposed to a fluid solution (which, in general, might not be a weak limit corresponding to any policy). Other times it is defined as fluid solution satisfying some *implications* of implementing a particular scheduling policy. This choice can be problematic as there is no guarantee that all the relevant implications of a given scheduling rule are properly captured in the fluid model.

In some special cases, more concrete results can be established.

Theorem 10. *Suppose an MQNET with two servers ($J = 2$) admits a fluid solution which diverges to infinity. Then, there exists a work-conserving scheduling policy in the underlying MQNET such that the network is not positive Harris recurrent.*

In fact, a stronger result holds—under this scheduling policy the queue lengths diverge to infinity with probability 1 as time diverges to infinity. This result still leaves open the intermediate case when the fluid model is not globally stable, and no fluid solution exists which diverges to infinity. Several more general converse results are known (see next section for references).

As far as obtaining tight stability characterization of fluid models or of stochastic MQNETs for that matter, the positive results are limited. The only known result concerning general networks is the following characterization of globally stable fluid networks with two servers.

Theorem 11. *There exists a homogeneous linear programming problem associated with an arbitrary fluid MQNET. When the MQNET has two servers ($J = 2$), the network is globally stable if and only if this linear programming problem has a nonzero solution. In the special case when the routing process is deterministic, namely all entries of $\mathbf{P}$ are zero or 1, one can compute explicitly a certain parameter ρ^* called maximum*

virtual traffic intensity. The fluid network is stable if and only if $\rho^* < 1$.

There are additional tight stability results which, however, concern networks with very specific assumptions, such as the four class two-server network Of Lu–Kumar, which is depicted in Fig. 1. Short of these results, there does not exist a general stability criterion for stochastic or fluid MQNET. The explanation for the lack of such results comes from negative results established in Gamarnik [11] and Gamarnik and Katz-Rogozhnikov [12], where the question is placed on an algorithmic theoretic framework. Specifically, it has been shown that stability of a multiclass queueing networks is an undecidable property, namely, it cannot be resolved using any effective computational procedure. Because of space constraint the notion of undecidability is not defined in this article; the interested reader is referred to a very nice book by Sipser [13] instead, or to any textbook on the theory of algorithms.

On the positive side, there are a variety of scheduling policies and their fluid counterparts which stabilize MQNET. For example, when the network has a special structure known as *re-entrant line* MQNET [6,14], it is known that two particular priority policies known as first-buffer-first-serve and last-buffer-first-serve stabilize the system both in fluid and stochastic setting. In more general setting, it is known that the so-called global FIFO (policy that gives priority to jobs which arrive earlier to the *entire* network) is stable [15]. Finally, fluid models play a critical role in the analysis of diffusion approximation of queueing networks, especially in the multiclass setting, and are connected to a very important concept of *multiplicative* state space collapse [16,17].

NOTES AND SOURCES

Instability phenomena in underloaded multiclass queueing networks were first observed by Kumar and Seidman [9], who demonstrated the existence of an unstable work-conserving scheduling policy. A similar phenomenon was described in a related work

by Lu and Kumar [8], who introduced the network, which is depicted in Fig. 1. Rybko and Stolyar [18] obtained a similar result in a similar network and used fluid model technique for their analysis. Bramson [19] and Seidman [20] have shown that these instability phenomena can take place even for the FIFO service discipline. A comprehensive reference for stability and positive recurrence properties of general state space Markov chains is Meyn and Tweedie [21]. Fluid models of queueing systems have been considered for a long time [1], with transport processes being one of the earliest applications. The applications to MQNET have been developed in a series of papers [5,18,22,23]. A good book reference for this topic is [10]. The results showing that stability of fluid models implies stability of underlying stochastic networks (Theorem 8) were established by Dai [5] for general multiclass queueing networks and by Stolyar [23] for networks with exponentially distributed interarrival and service times. Partial converse results were established by Dai [24], Meyn [25], and Puhalskii and Rybko [26]. Some counterexamples showing that stability of fluid models does not necessarily coincide with stability of stochastic networks, including Theorem 9, were obtained by Dai *et al.* [27] and Bramson [28]. Theorem 10 was obtained by Gamarnik and Hasenbein [29]. Tight characterization of stable fluid models with two servers (Theorem 11) was obtained by Bertsimas *et al.* [30] using a trajectory decomposition method, and in the special case of 0-1 matrices $\mathbf{P}$ by Dai and Vande-Vate [31] using the Lyapunov function technique. Stability of feedforward networks (Theorem 4) was established by Dai [5] for fluid networks, and by Down and Meyn [32] directly for stochastic feedforward networks. Stability of stochastic Jackson network with generally distributed interarrival and service times was shown by Sigman [33] and Meyn and Down [34], and for fluid models (Theorem 2) by Dai [5]. The undecidability results mentioned in the previous section were obtained by Gamarnik and Katz [11], building on an earlier work by Gamarnik [12] for stability of random walks and their fluid models in a nonnegative orthant [35]. For a good reference on Turing

machines and decidability (computability), refer to Sipser [13]. A comprehensive study of random walks in a nonnegative orthant can be found in Fayolle *et al.* [36].

FORECASTING APPROACHES FOR THE HIGH-TECH INDUSTRY

MICHAEL GILLILAND
SAS Institute, SAS Campus Drive,
Cary, North Carolina

Forecasting in high-tech industries is beset by most of the same challenges faced in other industries. However, two factors that make high-tech forecasting more difficult are frequent new product introductions (with short product life cycles) and long supply chain lead times (due to off-shore production). New products—since they have no sales history to go by—are inherently more difficult to forecast than existing products. Long supply lead times require forecasts to be made farther into the future—and longer range forecasts tend to be less accurate than forecasts for the near term. These challenges make it highly unrealistic to expect accurate forecasts in the high-tech industry, yet there are methods for high-tech organizations to deal with this extra uncertainty. This article will focus on two such methods: The “structured analogy” approach to new product forecasting and forecast value added (FVA) analysis. Neither approach can guarantee highly accurate forecasts (nothing can do that). However, these methods permit the high-tech organization to generate forecasts efficiently (in less time, at less cost), and to better understand and deal with the uncertainties and risks.

NEW PRODUCT FORECASTING

There are many types of new product forecasting (NPF) situations that high-tech organizations can encounter:

- new-to-the-world products (entirely new types of products),
- new markets for existing products (geographical expansion or new sales channels),
- refinements to existing products (such as “new and improved” versions, or packaging changes).

Kenneth Kahn’s book, *New Product Forecasting: An Applied Approach* [1], provides a practical “toolbox” approach to illustrate how new product forecasts can be generated. The approach can vary significantly depending on the nature of the new product (whether new-to-the-world or the simple refinement of an existing product), and the nature of the market into which it will be sold (new or existing). This article will focus on the forecasting of new products in existing markets, where the most commonly used method is forecasting by analogy. Forecasting by analogy assumes that demand for a new product will be similar to demand for *like-items* from the past. Like-items are identified by common attributes or other criteria, and the forecast for the new item is based on a composite of the sales history of the like-items.

The real estate market provides a good example of the use of analogies. To determine the listing price for a property that is new on the market, the sales agent will prepare a list of “comps” (comparable houses in the area) that are currently on the market or have been recently sold. The prices of these comps (which serve as like-items) are used to suggest an appropriate listing price for the new property (which is, in effect, a forecast of what the property should sell for).

All NPF forecasting methods utilize judgment to some extent. While the use of judgment is necessary, it is frequently biased with over-optimism, or can be overly influenced by recent events. Judgment can also be clouded by personal or political agendas, where the forecast is used to represent what the organization wants to happen, rather than what anyone honestly believes will happen.

In practice, the forecasting by analogy approach is subject to similar misuse. Like-items that failed in the marketplace

may be forgotten (or purposely ignored), leading to overly optimistic expectations for the new product. There is also the danger of overconfidence in the accuracy of forecasts for the new product, and failure to appreciate the true uncertainty and risks involved.

New Product Forecasting by Structured Analogy

An emerging method for new product forecasting helps address some of these concerns. The “structured analogy” approach utilizes data visualization and analytical software to augment the use of analogies with structured judgment. This approach seeks to remove judgmental bias by providing a historical context for each decision [2].

The structured analogy approach requires two types of data: (i) attributes (of prior products and new products) and (ii) historical sales (of prior products). Product attributes might include:

- Product type (PC, mainframe, router, cpu, graphics chip, sound card, etc.)
- Target Market (consumer, industrial)
- Time of introduction (summer, winter, fiscal quarter, etc.)
- Financial characteristics (price point, competitor prices, etc.)
- Physical characteristics (memory, storage, processor speed, case size, etc.)

Historical information on past new product introductions is also needed. Sales of all

prior new product introductions (e.g., the first 20 weeks) are extracted and manipulated to align them all on a common time scale (weeks since product release). This permits the sales profiles of like-items to be overlaid to allow for statistical and visual assessment of the range of past new product outcomes.

Structured Analogy Process

The structured analogy process for new product forecasting has six main steps:

Step 1: Query. Identify a set of *candidate* products that have similar attributes to the new product.

Step 2: Filter. Option to manually remove inappropriate or outlier products from the set of candidate products.

Step 3: Cluster. Cluster the candidate products according to their sales pattern and select the most appropriate cluster to serve as the *surrogate* products.

Step 4: Model. Select the most appropriate statistical model for the cluster of surrogate products.

Step 5: Forecast. Use the statistical model to generate a forecast for the new product.

Step 6: Override. Option to make manual adjustments to the statistical model’s forecast.

Figure 1 illustrates the result of the query step for DVD movie sales, where like-items (based on user-specified product attributes for Genre and MPAA Rating) have been extracted and their profiles aligned. These

Figure 1. Profiles of like-item sales over first 20 weeks.

Figure 2. Statistical forecast and option for manual override.

particular like-items display a common type of profile (sales rapidly fall after the first week of release), yet the volume of sales varies considerably (from under a thousand to nearly one million units in the first week).

Note that judgment was used to determine which attributes were most relevant (here, Genre and MPAA rating). Judgment is again used in the filter step, where the forecaster can remove items from the candidate pool. After the filtering is applied, the cluster step groups the remaining candidates according to similarity of their sales pattern. Again, judgment is applied to select which cluster is most appropriate for forecasting the new product. This forms the group of *surrogate* products which are used to create the forecast model.

The model step generates a statistical model fitting the surrogate cluster. This can be a simple composite average of all the surrogate patterns, or more elaborate modeling techniques may be used. Once the model is specified, the forecast step generates a forecast for the new product. The final override step allows the forecaster to manually adjust the system generated forecast, and pass the final forecasts to downstream planning systems (Fig. 2).

Applying the Structured Analogy Approach

The structured analogy approach can be useful in many (but not all) new product forecasting situations [3]. It augments human judgment by automating the historical data handling and extraction, by incorporating statistical analysis, and by providing visualization of the range of historical outcomes. Software makes it possible to quickly extract candidate products based on the user-specified attribute criteria. It aligns, scales, and clusters the historical patterns automatically, making it easier to visualize the behavior of past new products. This visualization helps the forecaster realize the risks, uncertainties, and variability in new product behavior.

Expectations for the accuracy of new product forecasts should be modest, and acknowledgment of this uncertainty should be at the forefront. The structured analogy approach allows the organization to both statistically and visually assess the likely range of new product demand, so that it can manage accordingly. Rather than lock in elaborate sales and supply plans based on a point forecast that is likely to be wrong (and

possibly very wrong), the organization can use the structured analogy process to assess alternative demand scenarios and mitigate risk.

Judgment is always going to be a big part of new product forecasting, but judgment needs assistance to minimize biases and keep it as objective as possible. While the structured analogy approach can be used to generate new product forecasts, it is also of great value in assessing the *reasonableness* of forecasts that are provided from elsewhere in the organization. The role of structured analogy software is to do the heavy computational work and provide guidance—making the NPF process as automated, efficient, and objective as possible.

FORECAST VALUE ADDED ANALYSIS

Forecast accuracy is largely determined by the nature of the demand pattern being forecast—its *forecastability*. Smooth, stable, and repeating patterns can be forecast accurately with simple methods, but the high-tech industry rarely enjoys this luxury. Instead, elaborate models and processes are developed to forecast the volatile demand patterns that high-tech organizations face. But do these costly and time-consuming efforts work—do they make the forecast any better than a simple model, such as a moving average? This is the question addressed by forecast value added (FVA) analysis [3].

Traditional forecasting performance metrics, such as mean absolute percent error (MAPE) indicate the magnitude of the forecast error. But traditional metrics tell the organization nothing about what accuracy is reasonable to expect, or whether their efforts are “adding value” by making the forecast better. By definition

FVA $\equiv$ The change in a forecasting performance metric that can be attributed to a particular step or participant in the forecasting process.

FVA analysis compares the forecast at each step in a process to the forecast in the prior step. For example, in the simple process shown in Fig. 3, the analyst override is compared to the statistical forecast (generated by the forecasting software), which in turn is compared to a “naïve” forecast. A naïve forecast is something easy to compute, requiring the minimum amount of cost and effort. Typical examples are a random walk (using the last known actual as the future forecast), a seasonal random walk (such as using the actual from the corresponding period last year as the forecast for each period this year), or a moving average. If a process step (such as an elaborate statistical model or a manual override) is not making the forecast better, it can be eliminated from the forecasting process.

FVA analysis is consistent with a “lean” approach to supply chain management. The method has been utilized at major organizations inside and outside the high-tech industry, as a way to identify the waste and inefficiency in a forecasting process. The naïve model provides what is, in effect, a “placebo” forecast against which all other efforts are compared. Many organizations have found that their elaborate forecasting processes are just making the forecast worse.

Figure 4 illustrates an FVA report for the process in Fig. 3. This “stairstep” report shows what each process step was able to achieve, and computes its “forecast value added” compared to prior steps. In this example, we see that the statistical forecast reduced forecast error (MAPE) by 10% points compared to the naïve model. The analyst override did perform 5% points better than the naïve model, but 5% points worse than the statistical model. In such a situation, the organization may decide to eliminate (or sharply restrict) analyst overrides, and rely on the statistical forecast.

FVA analysis has several uses in high-tech organizations. Given the volatile demand patterns common in high-tech organizations,

Figure 3. Simple forecasting process.

Figure 4. FVA report for simple forecasting process.

they tend to have unrealistic expectations for forecast accuracy. Achieving the desired degree of accuracy may be impossible, leading the organization to over-invest in the forecasting function rather than look for other (nonforecasting) solutions to their business challenges.

The naïve model used in FVA analysis provides a realistic baseline for forecast accuracy expectations. It is reasonable to expect the organization to forecast *no worse than* the naïve model, and any process steps making the forecast worse can be safely eliminated. Even after bad practices have been eliminated, it can be surprisingly difficult to forecast significantly better than the naïve model.

FVA Shortcut: In-Sample Analysis of Forecastability

FVA analysis can be viewed as an “after-the-fact” approach that compares the out-of-sample performance of a complicated statistical technique (or elaborate forecasting process) with the out-of-sample performance of a naïve method. As such, it is appropriate for evaluating an organization’s existing forecasting approach, and determining (based on historical performance) whether the organization’s forecasting activities were making the forecast any better—or just making it worse. Such information would be of great value if it were known *before* elaborate and expensive methods were enacted—to avoid

the cost of enacting those methods that will fail to provide improvement. As a shortcut to full FVA analysis, in-sample analysis of *forecastability* may provide some answers.

The Spring 2009 issue of *Foresight: The International Journal of Applied Forecasting* contains several articles on the topic of forecastability. As Editor Len Tashman states in his preview to this special section,

Assessing the forecastability of a time series can give us a basis for judging how successful we’ve been in modeling the historical data and how much improvement we can still hope to attain [4].

Analysis of forecastability can drive better decisions on the configuration of complex forecasting systems. For example, if a time series is found to be overly volatile and “nonforecastable,” then overly elaborate methods may tend to “overfit” the historical behavior and not generate better forecasts. In this situation a simple statistical technique (e.g., random walk, moving average, or single exponential smoothing) could be used to generate forecasts as accurate as can reasonably be expected given the nature of the behavior, with no further effort applied. Effort could instead be applied to the more forecastable patterns—those exhibiting systematic behavior—that could benefit from the application of more sophisticated modeling or process approaches.

In-sample analysis cannot provide the more thorough and definitive performance answers that FVA analysis can provide. However, it can be done “before-the-fact” of major resource investments (such as a new forecasting system, or a more elaborate process), and help drive more informed decisions on the likely value of these new investments.

Handling Unforecastable Demand

For items that are determined to be unforecastable, or at least not forecastable to the degree of accuracy desired, the organization can seek nonforecasting related approaches. Two such approaches are supply chain reengineering and demand smoothing.

When an organization’s supply chain is extremely fast and flexible, and it can respond to demand as it occurs, then highly accurate forecasting (at least at the product level) is no longer a requirement. Forecasting efforts can be pushed to higher levels of aggregation, focusing on raw materials, or staffing, or capacity requirements, rather than on individual products. The supply chain reengineering approach seeks improvements in supply chain performance, to render forecast accuracy less critical.

The demand smoothing approach endeavors to “make the demand forecastable” by minimizing organizational practices that increase demand volatility. Common sales, marketing, and financial practices (such as sales contests, pricing and promotional activity, and quarter end revenue targets), tend to increase the volatility of demand, and thus make it more difficult to forecast accurately. Policies and incentives (both internal, and for customers) can be redesigned to encourage more predictable behavior. This can result in better forecasts without any new investment in forecasting systems or processes.

SUMMARY

This article has addressed two frequently occurring problems in high-tech industry forecasting. Regarding new product forecasting, the structured analogy approach helps management better understand the

uncertainty in new product forecasts, and the likely range of outcomes. This avoids the common mistake of putting too much confidence in the forecast, and taking on unwarranted risks. The structured analogy approach does not assure highly accurate forecasts—no method can do that. Its purpose is to augment management judgment—delivering objective and data-based guidance on the reasonableness of new product forecasts, whether these forecasts were generated by the process itself or provided from elsewhere in the organization.

The objective of the forecasting process is to generate forecasts as accurate as can reasonably be expected, and to do this as efficiently as possible. Forecasts are often made worse by organization politics and personal agendas that contaminate the process with needless manual overrides and executive approval steps. Traditional forecasting performance metrics, by themselves, do not identify these wasted efforts. FVA analysis is a method now used, in high-tech and other industries, to identify wasted efforts that cost time and money, yet fail to improve the forecast.

INTRODUCTION

When selling similar products, mainly due to product substitution by customers in case of stock outs and price/brand concerns, demand for a particular product may depend on the inventory positions of other products. Thus, the effective demand for a particular product is crosscorrelated to the demand of other products. Also, demand for each product might be autocorrelated. Demand created by advertisement or price discounts today might reduce demand in the future. From time to time, the demand might also experience other disturbances that are due to the current economic or political conditions. These dependencies make it challenging for a firm to generate accurate demand forecast for each product and to determine the “right” order quantities so as to maximize its own profit. Survey results reported at the Harvard/Wharton Merchandising Effectiveness Project [1] have found that these subjective forecasts tend to have an average forecasting error of 50% or more. As a result, some firms buy too little of some products resulting in lost sales and profit margin, and some firms buy too much of some products resulting in excess supply that must be marked down after a while, frequently to the point where the product is sold at a loss. A survey conducted by

a major retailer and reported in the New York Times on June 2, 1994, concluded that 50% of customers did not purchase products when they visited the store and of these 40% stated they did so due to their inability to find a given product. Similar under- and oversupply costs have been reported for other products such as automobiles [2] and computers [3]. Demand uncertainty is highest when a new product is introduced against competition. In some industries, for example, in the pharmaceutical industry, firms prefer to be responsive to the customer demand and thus incur high inventory costs to reduce lost sale. This is where accuracy in forecasting becomes crucial.

Firms spend a great deal of time and resources trying to predict, as accurately as possible, the future demand for their products and services. Clearly, it is beneficial to know about the future, and, in most cases, the near future where accuracy is most needed. Knowing about the future enables making better decisions of ordering when inventories are reviewed—both in pull- and push-type systems. Also, production plans and resource scheduling are done more effectively in push-type systems if we have a good idea about the future.

Two issues that are of concern here are forecasting and inventory control for multi-item systems where demand for these items can be correlated, as well as temporally correlated for each item. Classical forecasting procedures are usually carried out for single items. Standard coverage of well-known text books includes the following topics: times series analysis, exponential smoothing methods (see *Holt–Winters Exponential Smoothing*), moving average (MA) methods, regression with various possible extensions [4–8]. These references also include the study of nonstationary autoregressive integrated moving average (ARIMA) models (see *Forecasting Nonstationary Processes*). Nevertheless, a number of procedures can be utilized for the forecasting activities under correlated demand. For example,

regression models can be utilized to express several dependencies. However, more specialized tools, for example, multivariate time series modeling, state-space methods (see ***Forecasting: State-Space Models and Kalman Filter Estimation***), are needed for the purpose of forecasting for multiple items with correlation across items and time.

Most of the initial work done in the area of inventory theory has ignored the correlation between demand for different items as well as time periods. Instead, the demand is assumed to follow an independent stochastic process in order to ensure tractability of analytical results. However, more realistic models incorporate the past history of the market on the present demand behavior. Intuitively, it can be said that autocorrelated demand would worsen performance measures such as expected number in the warehouse and expected number of stock outs. It is important to investigate how profound the effect of demand autocorrelation is on system performance. Blinder [9] investigates the change in the optimum price and optimum order size to the demand fluctuations and shows that they will be larger when demand is highly correlated. Kahn [10], assuming a first-order autoregressive, AR(1), demand model, demonstrates that the order size is more variable than sales if demand is positively correlated. Altioek and Melamed [11] study the impact of autocorrelation on several production/inventory systems. They consider three different environments; an M/M/1 (see the section titled “Single-Station Queues: CTMC Models” in this encyclopedia) type workstation receiving autocorrelated arrival process; an M/G/1 (see the section titled “Single-Station Queues: Non-CTMC Models” in this encyclopedia) workstation with deterministic processing times, and autocorrelated operation dependent time to failures; and a single-stage manufacturing process with a raw material buffer and finished product inventory. They incorporate autocorrelation in random elements in the system, such as demand, lead time, time to failure, and repair times and investigate the effect on some system performance measures, such as average product waiting/flow times, throughput, and customer service

levels. The authors conclude that finished product level and customer service level are highly affected by the autocorrelation in the demand process [11].

We think that the following questions are valid for inventory analysis:

- How can one represent the demand function(s) that consider(s) the existing correlation structure?
- How does the level of demand correlation affect order quantities and expected profits over time?
- What is the optimal inventory control policy under correlated demand?

The first question represents the forecasting aspect, and the second and third ones represent the inventory control aspect. We aim to overview the inventory approaches in order to ascertain the demand-forecasting requirements. We then review forecasting procedures that will be helpful in realizing the aforementioned inventory models.

The next section briefly discusses the previous work on single and multiple item inventory control under correlated demand. In the section titled “Evolving Forecasts Through Time”, we examine the notion of evolving forecasts, including the Martingale model of forecast evolution (MMFE). We then summarize our conclusions.

INVENTORY PLANNING UNDER CORRELATED DEMAND

The bulk of inventory theory is based on single-item problems, with known independent and identically distributed demand. For the newsvendor problem (single period), the optimal policy is given by the *critical fractile* solution for the optimal stock level S^* [12] (see ***Newsvendor Models***). In the case of a normally distributed demand with mean μ and variance σ^2 , the solution simplifies to

$$S^* = \mu + z\sigma,$$

where z is obtained by evaluating the cumulative distribution function of the standard normal at the critical fractile. Scarf [13] has

shown the optimality of (s_t, S_t) policy for the dynamic inventory control problem with setup cost, K , under the condition that the optimal value function at each period t is K -convex. In such a policy, it is optimal to order up to the optimal stock level S whenever the inventory level drops to the reorder level, s , or below. If the setup cost, K , is zero, the optimal policy reduces to the base-stock policy that prescribes ordering up to S whenever the inventory level is less than S . It was shown by Veinott [14] and Sobel [15] that under certain conditions the optimal base-stock policy is myopic, that is, it can be decided only by considering the current period. Myopic policies are easier to implement and thus are preferable to the more complicated time-dependent policies. Veinott [14] has extended his results on the optimality of myopic policies to the demand distributions that are independent but not identical as long as they are stochastically increasing over time.

In this section, we review inventory models with correlated demand. The subsections consider single/multi item–single location and single/multi-item–multiple locations, with correlated demand.

Single Item–Single Location with Correlated Demand

We first review a broader group of studies referred to here as *inventory problems under nonstationary demand*. In these models, the demand distribution can vary during each period and is considered mostly in the context of single-product single-firm inventory control. Karlin and Fabens [16] introduce a Markov-modulated demand model that depends on the changing environmental factors. In this model, environmental factors are represented as the states of a Markov chain (see the section titled “Discrete Time Markov Chains” in this encyclopedia) and the demand in any given period is a random variable with a distribution function that depends on the current state of the environment. Thus, in this model, demands are independent and identically distributed as long as the environment’s state remains the same. Aware of the complexity of the analysis, the authors concentrate on finding a single optimal ordering policy irrespective of the state of the

environment. Song and Zipkin [17] study the continuous-time problem where the demand process is a Markov-modulated Poisson process (MMPP). In such a process, demands arrive as a Poisson process with demand rate changing according to a Markov chain. They show that the optimal ordering policy is of state-dependent (s, S) -type policy when there is a fixed ordering cost in addition to the linear cost (see also [18]). Treharne and Sox [19] analyze the same model when the current state of the environment is not observable. They give heuristics and present computational results. Without assuming a Markovian structure on the environment, Morton and Pentico [20] study the finite horizon, zero lead time, nonstationary problem, and derive upper and lower near-myopic bounds. They assume that demands in successive periods are independent but not necessarily identically distributed. They develop a number of heuristics and show that the best near-myopic heuristic is robust. Anupindi *et al.* [21] studying the stationary lead-time problem, obtain near-myopic bounds and give heuristics. They show that the average error increases with increase in variance of the lead-time distribution. Bollapragada and Rao [22] examine a single-product, nonstationary inventory problem with both supply and demand uncertainty, capacity limits on ordering quantities, and service-level requirements. A scenario-based stochastic program for the static, finite-horizon problem, is presented to determine replenishment orders over the horizon. A heuristic based on the first two moments of the random variables and a normal approximation is proposed.

Other than on Markov-modulated structures, there are a few studies in the area of correlated demands. In these studies, it is assumed that the demand is correlated between products as well as time periods. Although it is very difficult to obtain analytical solutions under correlated demands, it is worth studying correlation since it tells something about the new information which is observed every period. Ray [23] studies AR(1) and MA(1) demand models under stochastic lead times. By writing the moment-generating function of lead-time demand

in terms of demand variance–covariance matrix, and the lead-time distribution, he obtains the first two moments of the lead-time demand. These moments are then utilized in computing the reorder level that will provide a specified service level [24]. Johnson and Thompson [25] consider a single product, periodic-review system under stationary and nonstationary demand processes with no fixed cost. There are linear holding and shortage costs and the deliveries are instantaneous. They show that under some additional assumptions on the demand process, the optimal policies are myopic. Miller [26] introduces a multiplicative AR(1)-type uncertainty on the demand process and shows the optimality of myopic base-stock policies. Lovejoy [27], assuming a more general dependent demand structure, gives conditions under which the optimal replenishment policy is myopic. In production/inventory systems, a certain amount of information becomes available as time advances from one period to the next. It is important to incorporate this available information into the planning decisions of the system. This task can be achieved by means of forecast revisions that include correlation and evolve through time. Charnes *et al.* [28] consider a periodic-review inventory replenishment model with an order-up-to policy for the case of deterministic lead times and a covariance-stationary stochastic demand process. A method is derived for setting the inventory safety stock to achieve an exact desired stock-out probability when the autocovariance function for Gaussian demand is known. Graves [29] considers a special nonstationary demand structure, where the demand follows an integrated moving average (ARIMA (0, 1, 1)) process. For this demand process, the optimal order-up-to level is characterized and implications are discussed. Urban [30] analyzes the effect of autocorrelated demand to determine reorder levels. Specifically, first-order autoregressive and moving average (ARMA) demand processes are examined. Finally, considering nonstationary, correlated and evolving stochastic demands, Levi *et al.* [31] provide an approximation algorithm to obtain computationally efficient policies with constant worst-case performance guarantees.

Another group of studies that can be placed in this category are models with inventory and/or backorder-dependent demand structures. Inventory dependent demand is a special case of the general nonstationary demand model; within this category, the backorder-dependent demand structure has attracted some attention, as it is frequently observed in practice. Argon *et al.* [32] propose a single item, periodic-review model to investigate the effects of changes in the demand process that occur after shortage realizations. They investigate a system where the demands in successive periods are deterministic, but the level is affected by the backorder realizations. Urban [33] develops a periodic-review model with products that have autocorrelated demand, as well as demands dependent on the amount of inventory displayed to the customer. Urban [34] gives a comprehensive review of inventory models with inventory-level-dependent demand.

Single/Multi-Item Multiple Locations with Correlated Demand

In multilocation problems, demand interactions among the locations can be modeled using correlation structures. The work by Federgruen and Zipkin [35] is one of the initial studies that consider demand correlation across locations. They approach the periodic-review problem via dynamic programming to provide results in line with Clark and Scarf [36]. Erkip *et al.* [37] investigate the single-warehouse, n -retailer, multiechelon supply-chain model by Eppen and Schrage [38], and extend the results to the case where demand is correlated across locations as well as through time. The extension of the model to multiple items is possible, as long as the correlation structure is known. Closed-form expressions are obtained for safety stock values. Gilbert [39] presents a multistage supply-chain model that is based on the ARIMA time series models. Given an ARIMA model of consumer demand and the lead times at each stage, it is shown that the orders and inventories at each stage also follow ARIMA models, and closed-form expressions for these models are obtained. Graves and Willems [40] consider a single-product problem with a short life cycle. Given

a short product life cycle, product demand is increasingly difficult to forecast and is never really stationary because the demand rate evolves over the life of the product. The problem of placing strategic safety stocks with minimum cost is studied. They extend previous results for stationary demand to the case of nonstationary demand.

Another line of research within the multiechelon inventory systems that consider demand correlations across the items is the research on postponement. Several researchers study the benefits of product and process design that calls for delaying the differentiation of products; in other words, defer the stage after which the products assume their unique identities. Note that the end products have correlated demands, and hence aggregating them in manufacturing will help reduce the expected costs. Lee and Tang [41] develop a simple model that captures the costs and benefits associated with the use of product differentiation issues and focus on products having only one point of differentiation. Garg and Tang [42] extend these results to product families which have several points of differentiation. The analysis indicates that demand correlations in addition to some other factors play an important role in determining which point of differentiation should be delayed. Aviv and Federgruen [43] characterize the benefits of delayed differentiation and quick response programs when sales forecasts are updated over time. They consider more general settings, where parameters of the demand distributions fail to be known with accuracy or where consecutive demands are correlated.

Another stream of models that are of interest is models with advance demand information (ADI). Among many recent articles, we summarize a few. DeCroix and Mookerjee [44] study a periodic-review problem in which there is an option of purchasing advance demand information at the beginning of each period. Gallego and Özer [45] model ADI through a vector of future demands and show the optimality of a state-dependent order-up-to policy. Contrary to assuming that advance demand information is always known, Tan *et al.* [46] investigate a periodic-review inventory policy with

stochastic demand and stochastic advance demand information. In this model, each signal of advance demand can be treated as a potential demand. The evolution of the ADI is modeled as a Markov chain. Finally, Tan [47] considers the demand-forecasting problem in a business-to-business environment, where some customers provide information on their future orders, that are subject to change. The inaccurate information is used to specify a metric that influences forecasting.

EVOLVING FORECASTS THROUGH TIME

Introducing updating procedures for forecasting brings the Bayesian approaches into picture. There are a number of inventory problems that incorporate the Bayesian approach in decision making. There are two types of approaches: one assumes fully observable demand and the other, partially observable demand. Scarf [48], Azoury [49], Eppen and Iyer [50], Hill [51,52], among others, have assumed fully observable demand. For example, Lariviere and Porteus [53], as an example, considered Bayesian updating with partially observed sales. There are a number of studies that consider the notion of quick response, and hence apply Bayesian updates of forecasts to planning problems. As an example, Milner and Kouvelis [54] propose a single-period inventory modeling framework, with two ordering opportunities. The second order reacts to updated demand information and potentially capitalizes on supply-chain flexibility. The authors analyze the total inventory cost of a firm for alternate demand types: the standard assumption of independent demand over the period, fashion-driven innovative products through a Bayesian model, and innovative products with evolving demand through a Martingale process (see the section titled “Martingales” in this encyclopedia). The three demand processes exhibit very different behaviors with respect to the value of the alternate forms of flexibility.

Modeling the evolution of forecasting has been studied in the literature by several researchers. Graves *et al.* [55] and Heath and Jackson [56] suggest a general descriptive

model that accommodates simultaneous evolution of demand for many time periods and captures correlations between products and time periods, which is named as the *Martingale model of forecast evolution (MMFE)*. They argue that the MMFE approach is preferred to a direct time-series approach since it can capture the potential impact of expert judgment other than past data information. Below, we give a brief description of the model.

Consider a multi-item environment. Let D_n^j denote a forecast vector for item j in period n . We assume that there are J items and the forecasts are available for M periods. Hence,

$$D_n^j = (d_{n,n}^j, d_{n,n+1}^j, \dots, d_{n,n+M}^j, \mu^j, \mu^j, \dots),$$

where $d_{n,n}^j$ is the demand realization for item j in period n , $d_{n,n+1}^j$ is the demand forecast for period $(n+1)$ made at period n . It is assumed that the periods beyond the forecast horizon have a demand forecast of μ^j (stationary).

The evolution of demand forecasts from one period to the next can be modeled according to either an additive evolution model or a multiplicative one. Here we present the MMFE method through the additive model. Accordingly, the new forecast for the $(n+1)$ th period demand can be written in terms of the previous forecast and an error term as

$$\begin{aligned} d_{n+1,n+1}^j &= d_{n,n+1}^j + \epsilon_{n+1,1}^j \\ d_{n+1,n+2}^j &= d_{n,n+2}^j + \epsilon_{n+1,2}^j \\ &\vdots \\ d_{n+1,n+M+1}^j &= \mu^j + \epsilon_{n+1,M+1}^j, \end{aligned}$$

where for $n \geq 1$, $\bar{\epsilon}_n^j = (\epsilon_{n,1}^j, \epsilon_{n,2}^j, \dots, \epsilon_{n,M+1}^j)$ is the vector that represents the evolution of demands and forecasts from period $n-1$ to n . Note that the first component $\epsilon_{n,1}^j$ is the one-step ahead forecast error. The $\bar{\epsilon}_n^j$ vectors are assumed to be independent, identically distributed, multivariate normal random vectors with mean 0. The demand forecast update equation states that as we get closer to a demand period, say period

$(n+1)$, by updating the forecasts for this period successively, we reduce the variability of forecast errors. These assumptions also imply that the i -th step-ahead demand forecast for any j , $d_{n,n+i}^j$, is a martingale, and it is the conditional expectation of the $(n+i)$ -th period demand, given the history up to time n [55,56]. The definition of $\bar{\epsilon}_n^j$ enables us to allow for correlation among future forecasts of an item, as well as cross-correlations among forecasts of different items for a given period, n .

The above structure holds under the assumptions stated by Heath and Jackson [56]. The methodology suggested by MMFE is useful, as it also incorporates consistent knowledge on the forecasts. Many extensions or analyses regarding MMFE are available. In the remaining part of this section we summarize some of these studies, which also have a relation to or application in the supply chain area.

Güllü [57] considers a single-item production/inventory system that incorporates forecasts into planning decisions. He uses an additive forecast evolution model, which is a special case of MMFE and is able to capture the structure of dependent and nonstationary demand. He assumes that the production capacity is limited and unsatisfied demand is backlogged. As a benchmark, he considers a standard inventory model, which assumes the same distributional properties of demand. The suggested model yields lower expected costs and inventory levels when compared to a standard inventory model. In a similar study, Güllü [58] investigates a two-echelon allocation model consisting of a depot and several retailers, again integrating forecast revisions. The depot does not hold any inventory and unsatisfied demand is backlogged. He compares this system to a standard allocation model. The standard model results in higher order-up-to levels and higher system costs. Toktay and Wein [59] study a capacitated single-item make-to-stock environment facing a stationary, correlated demand process. They utilize the MMFE approach to generate forecast revisions. The forecast updates are then incorporated into the system to obtain approximate results for the base-stock level

that yields minimum expected inventory holding and backorder costs. Iida and Zipkin [60] propose a dynamic inventory model with the MMFE model. As a special case, it includes the ARMA demand model, represented by MMFE. They combine the MMFE with a linear programming model of production/distribution system in order to find an economical safety factor level and quantify the effects of forecast error on the total system cost. Lu *et al.* [61], also considering the MMFE model of demand forecast evolution in a periodic-review inventory model, develop bounds on the optimal base-stock levels as was done in Iida and Zipkin [60]. In addition, they provide bounds on the cost error of any heuristic with respect to the optimal policy, which is computationally intractable to evaluate. They give the necessary and sufficient conditions for the optimality of myopic policies.

Dong and Lee [62] revisit the serial multi-echelon inventory system of Clark and show that the structure of the optimal stocking policy of Clark and Scarf [36] holds under time-correlated demand processes using an MMFE. Then, the authors extend the approximation to an autoregressive demand model.

Aviv [63] considers a supply chain in which the underlying demand process, possibly evolves according to a vector autoregressive time series. The author proposes an adaptive inventory replenishment policy that utilizes the Kalman filter technique (see **Forecasting: State-Space Models and Kalman Filter Estimation**).

FORECASTING PROCEDURES FOR CORRELATED DEMAND AND APPLICATIONS

A typical forecasting process involves analyzing historical data. Historical data may exhibit trends, seasonal variations, as well as correlations. Other factors may come into the picture such as impact of other products or services in the market on the demand of the product being forecasted. Typically, the performance of the forecasting process is evaluated on the basis of the relative error, that is the percentage difference of the actual from its forecasted value, or the mean-squared forecast error.

Time series analysis techniques are utilized to carry out the forecasting process. Demand for each product is forecasted over a planning horizon in such a way that the mean-squared forecast error is minimized. Standard time series analysis techniques consider correlation structures over time, but are not effective when there are multiple items with correlated demand.

One way of avoiding forecasting demands of multiple items with cross-correlation is to aggregate the items. On the other hand, there is a need to forecast at the item level, as well. The following is the question here: Is it better to forecast the aggregate (and hence utilize a top-down approach) and then disaggregate, or to forecast the individual items directly (and hence utilize a bottom-up approach), and then the total? In any specific application, it will be hard to say which one would be better, unless ample data is available to support both approaches. Of course, the general understanding and approach are to utilize, as much as possible, the possibilities brought by the available data. Note that there are examples of both; consider Zhou *et al.* [64], where a top-down approach is utilized, and Chen *et al.* [65], which presents different (but not independent) representations for a two-item forecasting problem—an example of the bottom-up strategy.

In case we only need to consider autocorrelation, demand data can be modeled either as a stationary ARMA process or a nonstationary ARIMA process with other controllable and uncontrollable inputs [4–8]. Stationary models keep their distributional behavior in equilibrium around a constant mean. On the other hand, the nonstationary, ARIMA, models have no constant mean level over time. Nonstationary data quite often arise in industrial forecasting. Demand processes could also be modified to incorporate the effects of external factors such as economic, political, and geographic conditions. For multi-item systems with cross-correlation, multivariate time series models [66] such as a vector ARMA(p,q) could be utilized.

Aviv [63], considering a two-stage supply chain, employs state-space methods for modeling demand process as vector AR(1)(VAR(1)) time series. The minimum mean-squared

error (MMSE) estimates of the demand can then be obtained recursively via the Kalman filter (see *Forecasting: State-Space Models and Kalman Filter Estimation*) as new observations are included over time. These observations may not include full demand information. The adaptive replenishments follow a base-stock policy that depends on the aggregate demand estimate during lead time.

In order to forecast intermittent demand, Croston [67] presents two separate exponential smoothing forecasts, one on the demand size and the other on the demand interarrival times. Several studies demonstrate that Croston's method performs better than some competing approaches [68,69]. Shenshstone and Hyndman [70] attempt to identify stochastic models that underlie Croston's method in order to obtain confidence intervals for the forecasts. One such model assumes a nonstationary ARIMA(0,1,1) time series model for both the demand size and the demand interarrival times.

There are a few studies that combine forecasting performance with inventory performance. The difficulty lies in creating benchmarks, and we believe that more work in this area is needed.

One example is by Sani and Kingsman [69] who compare various inventory replenishment heuristics of (s,S) type in addition to the comparison of forecasting methods for a low demand item.

Chen *et al.* [65] report another study that combines forecasting and inventory control. The authors use a bivariate VAR(1) time-series model to investigate the effects of aggregating two interrelated demands. The paper further explores the properties of the aggregated time series and provides guidelines for practitioners to determine proper aggregation and forecasting approaches. A method is proposed to estimate the parameters of the demand model.

Other examples are from the production planning environments where forecast procedures are integrated with the planning procedures. Heath and Jackson [56] combine the MMFE with a linear programming model of production/distribution system in order to

find an economic safety stock level and quantify the effects of forecast error on the total system cost. A similar study is carried out by Kayhan *et al.* [71], where the application of MMFE to an industrial case is considered. Procedures to set safety stocks for an LP (linear programming)-based production planning model are proposed utilizing forecast error correlations across items and time modeled by MMFE.

CONCLUSIONS

In this article, we consider single-/multi-item supply chains under stationary or nonstationary correlated demand. We review inventory approaches in order to establish the demand-forecasting requirements. We also discuss the notion of evolving forecasts, including MMFE. We summarize various approaches for forecasting the demand of such inventory systems.

Forecasting is a very important tool for supply chains. Customer behavior and retail performance are factors affecting the demand for products. More comprehensive approaches for forecasting are needed that will consider all aspects of demand. On the other hand, we observe that there are still challenges ahead in achieving well-performing plans in a dynamically changing, uncertain environment, for more classical forecasting.

INTRODUCTION

Most of our daily life phenomena can be recorded as time series, such as wind speed, heart rate, and stock exchange price. Sometimes, it is convenient to assume that there are exact mathematical formulas describing the dynamics of the observable stochastic process. Understanding the underlying mechanism of these processes is very crucial in engineering and science. Although it is impossible to fully understand all the details of processes relating to the outcomes of a process, it is intuitively reasonable to assume that there are rules behind observable measurements and, once we understand those, we can forecast how the time series may develop to some extent. However, real-life phenomena are rarely simple and usually involve many parameters and variables that can influence the results with different time lags with different degrees. Still, with careful control of the recording environment, it is possible to reduce unpredictable factors and forecast a process within a margin of confidence. To understand all those principles and rules controlling these black-boxed processes simultaneously is a really tough task. Therefore, we would like to study simple nonstationary paradigms before moving

to the more complicated time series. As mentioned, a straightforward assumption is that a process possesses certain fixed properties in itself such that it evolves with some principle. One of the most convenient properties in a process is stationarity. Stationarity in the strict sense means that the statistics of a stochastic process does not change with time, meaning

$$f_{x_1, x_2, \dots, x_n}(t_1, t_2, \dots, t_n) = f_{x_1, x_2, \dots, x_n} \\ \times (t_1 + \tau, t_2 + \tau, \dots, t_n + \tau), \quad (1)$$

where f denotes probability mass function and τ denotes a time lag and of any size. When a process fails to fulfill Equation (1), we claim that the process is not stationary in the strict sense. Stationary processes possess relatively stable statistical properties such as fixed mean and variance compared to nonstationary ones. Nevertheless, fixed mean and variance by themselves do not imply stationarity in the strict sense. Besides, with those fixed statistics we can begin predicting the foregoing process with more confidence and less complexity. The first section of this article focuses on some necessary background for methods that will be introduced later. In the second section of this article, we will present two well-known practical methods to forecast nonstationary processes.

BACKGROUND KNOWLEDGE

Stationarity

Stationarity in the strict sense is almost impossible in real life. Even a parametric simulated process can only theoretically have stationarity, not to mention a time series recorded from real-world signals which have much more complex dynamics. One main reason why we bring up stationarity is that no model can include all explanatory variables affecting on the process, not to mention some factors that are beyond one's control. Although we can hardly have a stationary

process in the strict sense, we want to take advantages of those convenient properties of stationarity when studying nonstationary time series. Fortunately, one can still claim that a process has stationarity in a wide sense if it has not only a fixed mean and variance but also time-invariant autocovariance. Still, even when a process has stationarity, it does not mean that one can fully describe the process with only deterministic terms. To better describe effectors that are not controllable in a process, we should model a process with one or several deterministic and random terms. Actually, it is the random terms that define whether the process is stochastic or not. To make a further step toward real-life processes, we do not deal with stochastic processes but nonstationary stochastic processes. One way to dissect a nonstationary process is to use the concept of piecewise stationarity. Even though the whole process is nonstationary, we can still treat each segment of a reasonable length as if they were stationary, after splitting it into segments. Based on piecewise stationary concept in time domain, one can make an analogue to time and frequency domain and that is the idea of local stationary wavelet analysis that will be introduced in nonparametric method section of this article.

Local Stationarity. One of the crucial parameters for using the piecewise stationary concept is how to choose the length of a segment that is neither too short for calculating statistical estimates nor too long so that the process is no longer stationary [1]. It should be noted that the criterion for selecting the segment length should always be dependent on the method that we are using in order to model the nonstationary process. For example, for a quasi-stationary process, the underlying assumption is that the parametric properties might change their states between different time segments. As a result, an ideal segment should not be too long to overlap segments having different parametric values. Compared to quasi-stationary processes, parameters of a time-varying autoregressive model do not suddenly change but gradually evolve with time. Proper selection of a method to model

a process depends on some basic properties of the raw data. For instance, a seismic wave recording or an electroencephalograph recording containing a seizure shows sudden state changes. As a result, it is reasonable to use a quasi-stationary method for modeling. For some other processes such as the population of some species or the price of a stock, one might only be interested in their smooth evolution property instead of their sudden change due to special or dramatic events, so it would be reasonable to use the time-varying autoregressive model, which will be introduced later on in this article. For more details of segmentation implementation, readers are referred to the work of Appel and Brandt [1], and Adak [2]. Those methods of modeling a nonstationary process are called *parametric methods*. In addition, one can use nonparametric methods that do not assume the existence of a model or distribution family in a process. Compared to parametric methods, nonparametric methods still involve choosing the parameter to some extent but not as much as in parametric methods. If one intends to observe a nonstationary process as a piecewise, quasi, or evolutionary stationary process, a very well-known and widely used nonparametric tool called *time-dependent spectrum* in the time–frequency analysis field can be used. For a more detailed introduction of the classes of nonstationary process, readers are referred to the work of Adak [2].

Parametric Method for Analyzing Nonstationary Process

The benefits of using a parametric method are its simplicity and lucid structure. The main feature of parametric methods is the use of parameters as structural elements to introduce interpretation and interaction so that one can reduce the ambiguity within the data itself. This, however, might be achieved at the risk of misinterpretation [3]. Some other parametric approaches are based on specific assumptions that process outputs belong to the family or families of the distributions used in the model or can be described as the output of a stochastic process [4], whereas nonparametric approaches do not impose specific constraints with regard to

the distribution family. One has to first carefully scrutinize the statistical properties of the observed data and the necessary assumption for the parametric method being applied for the estimation [5]. In sum, parametric methods are beneficial only if there is a strong reason to look at the process in a particular structural way or as a member of a certain distribution family. As one can imagine, a parametric approach might not perform well on a process having a huge future random term which does not constantly fall into any distribution family and a weak link between current and future states of the process. The time-varying autoregressive (AR) model [6], just like a stationary process, can use a parametric or nonparametric method to start the analysis on a nonstationary process. One of the most commonly used model for simulating or fitting nonstationary time series is the time-varying AR model. A p th order linear time-varying AR model can be written in a general form as

$$x_k = \sum_{i=1}^p \phi_{i,k} x_{k-i} + \varepsilon_k, \quad (2)$$

where $\phi_{i,k}$ are time-varying parameters that differentiate a time-varying AR model from an AR model that has fixed coefficient ϕ_i instead of $\phi_{i,k}$. The main difficulty of using a parametric model for analysis lies in choosing proper values for parameters. As Equation (2) shows, p and $\phi_{i,k}$ are parameters that need to be chosen on the basis of the training data, while ε_k is a zero-mean white-noise process. One advantage of a parametric method is that it renders a lucid dynamic relationship between data points and gives us some sense of how data evolve over time. However, the model may not be unique because of the uncertainty of parameters. We should bear in mind that we can fit models of different orders into the same data sets. In this case, the time-varying AR model parameter values ($\phi_{i,k}$) might be significantly different especially for a complex data set. Several ways have been proposed to find the optimal order of an AR model, such as the Akaike information criterion (AIC) [7], Bayesian information criterion (BIC) [8], and the likelihood ratio test [9,10]. Once the order of

the AR model is decided, ϕ_i are calculated from Yule–Walker (YW) equations. There exist other methods for estimating regression coefficients such as Burg’s method (Burg), the least-squares (LS) approach, modified covariance method, covariance method, parametric spectral estimation method, Prony’s method, and so on. However, choosing the order of a time-varying AR model is more complex than choosing an AR model itself. A recently proposed method for the time-varying AR model order uncertainty is the generalized likelihood ratio test [11].

Autoregressive Integrated Moving Average (ARIMA) Model. In this case, we deal with nonstationary processes whose derivative, of proper order, is a stationary process. Compared to an autoregressive moving average (ARMA) model, which can be represented by the bilinear equation

$$x_n = - \sum_{k=1}^p a_k x_{n-k} + \sum_{k=0}^q b_k u_{n-k}, \quad p, q \in \mathbb{Z}, \quad (3)$$

where $\{u_n\}$ is a Gaussian white noise process, an autoregressive integrated moving average model (ARIMA) can exhibit not only ARMA but also nonstationarity having neither a fixed mean nor a fixed variance. A very important property of ARIMA is that, if one takes the d th derivative of the process, it will result in a stationary process that can be represented by another ARMA model $\{x_n\}$ [12]. This relationship can be represented by the following equation:

$$\Delta^d z_n \triangleq x_n = - \sum_{k=1}^p a_k x_{n-k} + \sum_{k=0}^q b_k u_{n-k}, \quad p, q, d \in \mathbb{Z}. \quad (4)$$

This also gives us a powerful linkage for changing a nonstationary process into a stationary one which can be more easily analyzed. However, one should notice that the high-frequency components of the process would be amplified after differentiating [13]. By considering an ARMA (p, q), with $q \leq p$, it is possible that the AR part has more terms than the moving average (MA) part. The

realization of an ARMA state space model is given as:

$$\tilde{x}_{k+1} = \begin{bmatrix} -a_{1,k} & 1 & 0 & 0 & \cdots & 0 \\ -a_{2,k} & 0 & 1 & 0 & \cdots & 0 \\ -a_{3,k} & 0 & 0 & \ddots & \ddots & \vdots \\ \vdots & \vdots & \vdots & \ddots & 1 & 0 \\ -a_{p-1,k} & 0 & 0 & \cdots & 0 & 1 \\ -a_{p,k} & 0 & 0 & \cdots & 0 & 0 \end{bmatrix} \tilde{x}_k + \begin{bmatrix} b_{1,k} - a_{1,k} \\ b_{2,k} - a_{2,k} \\ \vdots \end{bmatrix} \tilde{u}_k, \quad (5)$$

$$z_k = [1 \ 0 \ \cdots \ 0] \tilde{x}_k + u_k, \quad (6)$$

where $\tilde{x}_k = \{x_k, x_{k-1}, \dots, x_{k-p+1}\}^T$ and $\{\tilde{u}_k\}, \{u_k\}$ are both Gaussian white-noise processes. The tilde indicates a vector. If we denote the transition matrix as F_k , the noise coupling matrix as G_k , and the observation matrix as $\tilde{h} = [1, 0, \dots, 0]$, Equations (5) and (6) and Equations (3) and (4) become

$$\tilde{x}_{k+1} = F_k \tilde{x}_k + G_k \tilde{u}_k, \quad (7)$$

$$z_k = \tilde{h} \tilde{x}_k + u_k. \quad (8)$$

We can make a comparison between ARIMA and time-varying AR which has the following dynamic matrix form:

$$\tilde{x}_{k+1} = F_k \tilde{x}_k + \varepsilon_k, \quad (9)$$

$$z_k = \tilde{h} \tilde{x}_k, \quad (10)$$

where ε_k is a zero-mean innovation with time-varying variance and

$$F_k = \begin{bmatrix} \phi_{k,1} & \phi_{k,2} & \cdots & \phi_{k,p-1} & \phi_{k,p} \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & 0 & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix}. \quad (11)$$

Bayesian Autoregressive Model. Another widely used parametric model for time series is the Bayesian autoregressive model. There are a number of Bayesian forecasting

techniques that are available in the literature. A Bayesian multivariate regression was used to analyze the vector autoregressive model. The model is provided by the equation

$$x_t = \tilde{v} + A_1 y_{t-1} + \cdots + A_p y_{t-p} + \tilde{u}_t, \quad (12)$$

where $\tilde{x}_t$ is a column vector and A_i are the autoregressive coefficients, $\tilde{v}$ is the vector of intercepts, and u_t is the Gaussian white noise. Now, the above can be rewritten as the Bayesian multivariate regression model. A detailed analysis of the model is provided in the refs 14 and 15. A natural extension of the multivariate regression model would be the multivariate dynamic model in the previous section. This provides us with possibility of discounting, which is a process where more weights can be added to the most recent information and external information can also be considered. Barnett *et al.* [14] provide a Bayesian modeling of autoregressive time series through parameter estimation, outlier identification, and interpolation of missing information. They provide a Markov-chain Monte Carlo sampling technique to simultaneously handle this and demonstrate it through a real-life example. A Bayesian approach to nonstationary process has also been studied [15].

In this procedure, the data is divided into blocks and an autoregressive model is fitted to each block. The smoothness parameter that is controlled by the autoregressive coefficients of successive blocks is determined by AIC or BIC. McCullough and Tsay extend the Bayesian analysis for autoregressive time series in order to predict the time point at which the variance and mean shifts occur [16]. They use a Gibbs sampler to make random draws from conditional distributions of the variables involved, which are related to the probability of shift at a given time point. A number of surveys and expository articles that deal with Bayesian forecasting techniques are available in the literature for an interested reader [17]. Besides parametric and nonparametric methods, there are semiparametric models [18] combining both parametric distributions and nonparametric

models. There have been works using semi-parametric models to analyze nonstationary processes. Interested readers can refer to Velasco [19] and Damian *et al.* [20] for details. One should notice that, since semi-parametric methods contain parametric components, they make the assumptions that are made in the parametric methods and might suffer from the same disadvantages as the parametric methods.

Time–Frequency Analysis: Wavelet Transforms

A useful tool for time–frequency analysis is called *wavelets*. Most of the stationary processes are generated in the time domain and also recorded in time domain. However, a weakly stationary process can be characterized by its frequency components. That is why Fourier transform is so widely used in almost every field of science and engineering. The Fourier transform represents a process formula as a superposition of pure frequencies, as follows:

$$X(f) = \int_{-\infty}^{\infty} x(t)e^{-i2\pi ft} dt, \quad (13a)$$

where i denotes an imaginary unit.

Although the representation through Fourier transform can clearly show those weighted components of a process in terms of frequencies, it does not include any time component. One can hardly perceive when those frequency components participate in a process. Especially, for real data such as seismic waves or biomedical signals, a functional transform showing results in both the time and frequency domains can be much more informative and intuitive. A very widely used time–frequency analysis is the wavelet transform, which renders a perspective with both time and frequency resolutions by imposing a mask function before the original signal as

$$X(t, f) = \int_{-\infty}^{\infty} w(t - \tau)x(\tau)e^{-i2\pi f\tau} d\tau, \quad (13b)$$

where $w(t - \tau)$ is the mother wavelet function. When $w(t - \tau)$ is a rectangular window, the above equation is also called *short-time Fourier transform*, *windowed Fourier transform*, or *time-dependent Fourier transform*.

One may see the potentiality of wavelet from Equation (13b) that it has a t parameter that can characterize the signal at a certain range in time domain. As we can imagine, a real-life signal such as seismic waves that shows the characteristics of a short impulsive feature can hardly be described merely through Fourier transform decomposing the seismic wave into a combination of sinusoidal functions covering from negative infinity to infinity [21]. Because of the dual property of a wavelet both in the time and frequency domains, one can not only use a wavelet for time–frequency analysis but also for denoising a process that has noise with a certain unique frequency band and that happen sporadically with time [22,23].

Local Stationary Wavelets. Assuming that a process $\{X_t\}, t \in \mathbb{Z}$ possesses stationarity, we can estimate second-order statistics such as variance or auto-covariance through only a segment of observation and have confidence in the estimated statistics because its stationarity has rendered characteristic quantitative homogeneity. As we have longer term observation, we can estimate statistics better through prolonging our observational period. In contrast, for a nonstationary process, if we assume that the variance of a process changes slowly over time, saying that variance is a continuous and differentiable function of time, the variance can still be estimated with certain precision by gathering information around the time point of interested variance. This demand exactly fits the property of wavelet transform, which preserves local characteristics of a process to some extent on both time and frequency domains. A statistically slowly changing process can be called a *local stationary process* [24]. For a covariance-stationary process X_t , there is a Cramér representation

$$X_t = \int_{(-\pi, \pi]} A(\omega) \exp(i\omega t) dZ(\omega), \quad t \in \mathbb{Z}, \quad (14)$$

where $Z(\omega)$ is a stochastic process with orthonormal increments [25]. Nonstationary processes can be written in almost the same way as Equation (14) but $A(\omega)$ is replaced by a function of time. Along with

the same rationale, a nonstationary process can be represented using local stationary wavelet and nondecimated discrete wavelets $\psi_{j,k}(t)$, $j = -1, -2, \dots, k \in \mathbb{Z}$, where j indicates the scale and k indicates time location. To express a local stationary process, one can write it as

$$X_t = \sum_{j=-J}^{-1} \sum_{k \in \mathbb{Z}} w_{j,k} \psi_{j,k}(t) \xi_{j,k}, \quad (15)$$

where $\xi_{j,k}$ is mutually orthogonal zero-mean random innovation. From Equations (14) and (15), one should notice that $w_{j,k}$ in Equation (14) corresponds to $A(\omega)$ in Equation (14) and both of them indicate the amplitude of each analysis component. One should also notice that $\psi_{j,k}(t)$ is a replacement of the Fourier harmonics $\exp(i\omega t)$, in Equation (14). The subscript indices j and k in $w_{j,k}$ represent scale and time location, respectively, just like those in $\psi_{j,k}(t)$. The reason for using nondecimated discrete wavelet is that it can be shifted to any time point and not only confined to shifts of 2^{-j} compared to discrete wavelet. Note that nondecimated wavelets do not have orthogonalities and are an over-complete collection of shifted vectors [24]. An example of discrete nondecimated wavelet is the Haar wavelet. Nason *et al.* [24] also proposed the evolutionary wavelet spectrum (EWS) to quantify how the size of $w_{j,k}$ changes over time and defined it as

$$S_j(z) = S_j(k/T) \approx w_{j,k}^2. \quad (16)$$

Note that in EWS, $S_j(z)$ still has resolution in both frequency and time domains but with a different timescale which rescales the whole observation time into $z \in (0, 1)$: saying that the rescaled time z is calculated by dividing k by the whole observation time length T , and $k = 0, 1, \dots, T-1$. Our goal is to estimate the variance of a local stationary process. To accomplish that, one way is to put together the localized information around the time point of interest, with the concept of local stationary wavelet and EWS. Let $c(z, \tau)$ represent localized autocovariance and be defined as:

$$\begin{aligned} \lim_{T \rightarrow \infty} \text{cov}(X_{[zT]-\tau}, X_{[zT]+\tau}) &= c(z, \tau) \\ &= \sum_{j=-\infty}^{-1} S_j(z) \Psi_j(\tau), \end{aligned} \quad (17)$$

where $\Psi_j(\tau)$ is the autocorrelation function of $\psi_{j,k}(t)$ and $[\cdot]$ denotes the integer part of the real number. That is,

$$\Psi_j(\tau) = \sum_{k=-\infty}^{\infty} \psi_{j,k}(0) \psi_{j,k}(\tau). \quad (18)$$

Once the localized autocovariance is defined, localized variance at time z can be defined by

$$v(z) = c(z, 0) = \sum_{j=-\infty}^{-1} S_j(z). \quad (19)$$

Another evidence for justifying that a time–frequency domain autocovariance in terms of wavelets preserves the intuitive sense of an autocovariance in time domain can be seen through the relationship between Allan variances [26], which is defined by

$$\bar{X}_t(\tau) = \frac{1}{\tau} \sum_{n=0}^{\tau-1} X_{t-n}, \quad (20)$$

and Haar wavelet variances [24]. It is worth noting that Allan variance involves merely localized time-domain representation. However, a Haar wavelet involves both localized time and frequency domain representations and, then, an Allan variance is

$$\sigma_X^2(\tau) = \frac{1}{2} E(|\bar{X}_t(\tau) - \bar{X}_{t-\tau}(\tau)|^2), \quad (21)$$

while a Haar coefficient on finest scale or smallest dilation, $j = -1$, on any translation or location k is

$$\begin{aligned} \bar{d}_{-1,k} &= 1/[\sqrt{2}(X_{2k+1} - X_{2k})], \\ k &= 0, \dots, T/2 - 1, \end{aligned} \quad (22)$$

then we can see that

$$\text{var}\{\hat{d}_{j,k}\} = E\hat{d}_{j,k}^2 = \tau_j \sigma_X^2(\tau_j). \quad (23)$$

Forecasting

Based on the background mentioned above, we are ready to present prediction algorithms for nonstationary processes. A Kalman filter can be used for prediction on a more parametric basis. Compared to a Kalman filter, local stationary wavelets do not necessarily need to fit data with a parametric model and may concern only measurement *per se*. In contrast to parametric analysis, a nonparametric analysis forsakes the idea that there is a model governing evolution of data, which in any case lets the observation characterize the data by itself.

Kalman Filter. The Kalman filter is a recursive filter which can estimate linear dynamic parameters given some noisy measurements. Here we should not take the word “filter” as only a passive data-processing algorithm but think of it as a computer program that can gather input information in order to optimally estimate the transition of a system. Another problem arises when one needs to determine whether a Kalman filter is able to properly estimate a nonstationary process. As we mentioned in the previous section on ARIMA, a nonstationary process can be treated as a stationary ARMA after taking appropriate orders of derivative on the ARIMA [27,28]. As a result, we can focus on only ARMA now without loss of generality, and the following is a predictive method using the concept of Kalman filter. If an ARIMA fails to be differentiated properly into an ARMA, one can still implement a Kalman filter onto an ARIMA process even if the ARIMA has missing observations [29]. Since the Gaussianity and linearity possessed in a Kalman filter are independent of the nonstationarity of a process, we can assume linearity and Gaussianity in a Kalman filter and use it to analyze a nonstationarity process without loss of generality. Readers are referred to Gordon [30], and Kitagawa [31] for more detailed methods for modeling non-Gaussian state space. According to McGonigal and Ionescu [28], a state space model must be found first before applying a Kalman filter for prediction. They proposed a simplified model based on Aoki’s method

which could model an ARMA state space [32]. In Huang *et al.*, [13], the authors gave an implementation of using Kalman filter to predict a time-varying AR-2 process, which is a nonstationary and Gaussian–Markovian process and can be described in a general form as

$$x_k = \sum_{i=1}^p \phi_{i,k} x_{k-i} + \varepsilon_k + \sigma_k. \quad (24)$$

If one compares Equation (24) with Equation (2), one should notice that the time-varying model mentioned in this section has an extra term σ_k . Huang added σ_k , a time-varying term, to better track the moving trend of wind speed, which is one of the applications discussed in his work. To describe this time-varying AR-2 model in a matrix form, we first define a vector space $\Psi = (\phi_1 \ \phi_2 \ \sigma)^T$ containing parameters that we need to decide later and then represent the differences of parameters as they evolve with time using their dynamic relationship

$$\begin{pmatrix} \Psi_k \\ \Gamma_k \end{pmatrix} = \begin{pmatrix} I & I \\ 0 & H \end{pmatrix} \begin{pmatrix} \Psi_{k-1} \\ \Gamma_{k-1} \end{pmatrix} + \begin{pmatrix} 0 \\ I \end{pmatrix} \Omega_k, \quad (25)$$

where I is the identity matrix and Ω is a zero-mean white-noise vector. If we define H as an identity matrix, Γ_k is a random walk process and Ψ_k ends up being an integrated random walk process. If H is a zero matrix, then Γ_k should be a white Gaussian noise process and Ψ_k ends up being a random walk process. Note that the role of Γ_k is the first-order difference of Ψ_k and it describes the changes between Ψ_k and Ψ_{k-1} as time moves on. We can predict our nonstationary process, which is a time-varying AR-2 model, once the crucial step of choosing parameters in our model is carried out, and this can be accomplished by the Kalman algorithm. A general way of implementation of a Kalman filter starts with setting up the parameter model in the state space form as

$$\tilde{z}_k = A \tilde{z}_{k-1} + B \tilde{\zeta}_k, \quad (26)$$

$$\tilde{y}_k = C \tilde{z}_k + \tilde{\eta}_k, \quad (27)$$

where $z_k = \begin{pmatrix} \Psi_k \\ \Gamma_k \end{pmatrix}$ is the state vector, A is state matrix, B is input matrix, C is output matrix, and y_k is the observation vector of dimension p , meaning $\tilde{y}_k = (x_k \ \cdots \ x_{k-p+1})^T$.

Furthermore, $\tilde{\zeta}$ and $\tilde{\eta}$ are zero-mean white-noise vector processes. Given the estimation of z_k as $\hat{z}_k$, one can write the estimation dynamics as

$$\hat{z}_{k|k-1} = A\hat{z}_{k-1}. \quad (28)$$

And then we define the covariance matrix of estimation errors $P_k = \langle (\hat{z}_k - \tilde{z}_k)^T (\hat{z}_k - \tilde{z}_k) \rangle$, state disturbance matrix $R = \langle \tilde{\zeta}_k^T \tilde{\zeta}_k \rangle$, and the noise variance matrix of measurement $Q = \langle \tilde{\eta}_k^T \tilde{\eta}_k \rangle$ where $\langle \cdot \rangle$ denotes expectation. $\hat{z}_k$ can be calculated through a recursive algorithm [33].

Local Stationary Wavelet (LSW). Given a series of t measurements, in which we want to use those t measurements to predict the process step h after t , we can write our interested process as $X_{0,T}, \dots, X_{t-1,T}$ where $T = t + h$ and then define a linear predictor as

$$\hat{X}_{t+h-1,T} = \sum_{s=0}^{t-1} b_{t-1-s,T}^{(t,h)} X_{s,T}. \quad (29)$$

The next task is to optimize $b_{t-1-s,T}^{(t,h)}$ so that mean square prediction error (MSPE) $E(\hat{X}_{t+h-1,T} - X_{t+h-1,T})^2$ is minimized. To utilize the properties of local stationary wavelet (LSW), we represent the approximate MSPE in a wavelet matrix form

$$\begin{aligned} E(\hat{X}_{t+h-1,T} - X_{t+h-1,T})^2 \\ = \tilde{b}_{t+h-1}' B_{t+h-1,T} \tilde{b}_{t+h-1}, \end{aligned} \quad (30)$$

where $\tilde{b}_t = (\tilde{b}_{t-1,T}^{(1)}, \dots, \tilde{b}_{0,T}^{(1)})$, and $B_{t,T}$ is the covariance matrix consisting of localized autocovariance whose size is $(t+1) \times (t+1)$ and (m,n) th element is $c(n+m/2T, n-m)$, which is the localized autocovariance involving the wavelet form as mentioned in the background LSW section. The whole procedure of forecasting a nonstationary process with long enough observations involves two training sets. First, divide the long-term

observations into two training sets and then use the first one to generate the $B_{t,T}$ matrix. Second, use the other training set to optimize $\tilde{b}_t$ vector such that MSPE is minimized. In practice, the first part involves selection of two more parameters, and readers are referred to Fryzlewicz *et al.* [34] for specific details. Once those parameters are selected, the model would be ready for prediction.

APPLICATION

In Gomez *et al.* [29], Kalman filter method is applied to five datasets (totally 621 observations) of monthly observations on international airline passengers. An ARIMA model is used to fit observations, and all parameters were estimated before the application of Kalman filter. Root mean square errors (RMSE) of predictions of 1 month ahead up to 12 months ahead were reported. For the one-month-ahead prediction, the RMSE is around 0.045 for all five datasets. For 12-month-ahead prediction, the RMSE increases to more than 0.080 for all five datasets. In Fryzlewicz *et al.* [34], LSW is applied to forecast how the wind speed anomaly index evolves up to nine steps (nine months) ahead. Modeling the wind speed anomaly index with LSW is intuitively legitimate because the variation of wind speed is expected to be smooth. After parameter training, their one-step-ahead prediction can have more than 90% of actual observations fall in the 95% prediction interval which is based on the assumption of Gaussianity and defined as

$$I_t = [-1.96\hat{\sigma}_t + \hat{X}_t, 1.96\hat{\sigma}_t + \hat{X}_t]. \quad (31)$$

The results of nonstationary forecasting in other references using other methods also are promising for only one-step-ahead prediction but not accurate enough for a longer prediction horizon.

MULTIVARIATE PROCESS MODELING AND FORECASTING

In this section we discuss in brief some extensions for multivariate nonstationary time series forecasting for the multivariate

processes. A direct extension of multivariate models can be obtained from the univariate models by recording the observational errors at each time point as vectors instead of scalars. Thus, the observational errors obtained from the multivariate models follow a multivariate normal distribution. However, the theory for univariate models cannot be directly extended to the multivariate models because of the uncertainty in the variance matrix and hence we do not have the luxury of performing the same conjugate analyses as what we did for univariate models. In other words, the univariate theory could be extended only under the assumption that the observational error variance matrix is known ahead of time, and this is usually not the case. For $t = 1, \dots$, we have $\tilde{x}_t$ as a column vector with r observations. The multivariate model is provided by the four-tuple system: $\{F, G, V, W\}_y = \{F_t, G_t, V_t, W_t\}$, where F_t is $n \times r$ dynamic regression matrix, G_t is $n \times n$ state evolution matrix, V_t is $r \times r$ observational variance matrix, and W_t is a $n \times n$ evolution variance matrix, and we assume that all of them are known. Now, the defining equations of the model are given by

$$\tilde{x}_t = F_t \tilde{\theta}_t + \tilde{v}_t, \quad \tilde{v}_t \sim N[0, V_t], \quad (32)$$

$$\tilde{\theta}_t = G_t \tilde{\theta}_{t-1} + \tilde{\omega}_t, \quad \tilde{\omega}_t \sim N[0, W_t], \quad (33)$$

where $\tilde{v}_t$ and $\tilde{\omega}_t$ are the error sequences that are internally mutually independent and $\tilde{\theta}_t$ is the n -dimensional state vector. Equation (32) provides the sampling distribution of $\tilde{X}_t$ conditional on $\tilde{\theta}_t$, and Equation (33) is the state equation that provides the state of the system over time. Now that the variance matrices are assumed to be known, we can directly extend the methodologies developed for univariate models to the above multivariate model. A detailed analysis of this extension is provided in Ref. 35. A number of models have been developed for the case where the covariance matrix for the multivariate time series is not known ahead of time. A framework was developed for this case [36,37]. The model assumes that the analyses are performed on different time series that are alike and each of these time series follow the case of univariate dynamic model. The components of the four-tuple systems are assumed

to be common for each of the time series and the defining equations for each of the time series is provided in a similar manner. Once again, the error sequences in the equations are independent. This framework permits the development of various models for the multivariate time series analysis with unknown variance matrix. The observational error vector is assumed to follow a multivariate normal distribution and the evolution error matrix follows a matrix-variate normal distribution. Several models were developed from this framework and extended [38–40].

CONCLUSION

In this article, the concept of nonstationarity in stochastic processes was presented, explaining how to preprocess nonstationary processes and forecast their trend parametrically and nonparametrically. The applications of forecasting nonstationary processes span widely from air pollution to electroencephalograph analysis. Those applications and their forecasting results in detail can be found in the respective references. Besides these two methods we introduced, there are other methods for forecasting a nonstationary process. Here, we only present a general concept of this topic. In different applications, there may be a favorable method with more specific parameter selection criteria to better model and forecast the process.

INTRODUCTION

Humans observe their environment, learn its properties, and by forecasting the future events, they make plans to influence future outcomes to their benefit. There are risks that those plans, for which actions are based, are not good at all. Hence, it is desirable to set up expectations, based on the detailed analysis of empirical evidence and sound knowledge in order to reduce the risk of future regrets.

Forecasting methods to set up reasonable expectations for the future events are mainly based on the properties of relevant historical data (time series) assuming that the environment will not change significantly. Forecasting models express relationships between what the past evidence shows and what could possibly take place in the future.

System models are useful concepts to represent relations, interactions, and to build up tools for predicting the collective behavior of entities. An input–output model expresses the behavior of an open system that interacts with its environment, in a causal manner (the past and the present of the system shape its future), which takes from its environment (input, or stimulus) and gives to its environment (output, or response). If one is interested in the behavior of an observable (measurable) open system, then one should observe the system for some time for

stimulus–response relations and construct an input–output model that suitably fits to these observations.

A similar causal model (local in time) is the state-space representation of an open system, where the underlying system's behavior is represented by its state and its response to an input at that state. The collection of all possible (admissible) states of a system is known as the *state-space* [1–3]. In order to predict the future states of a dynamic system, with minimum mean square error, we can design a recursive predictor based on the current estimate and the current filtered estimation error. The best estimate of the state of a linear stochastic system from partial observations is known as *Kalman filter* [4,5] (also known as *Kalman–Bucy filter*).

Previous work on this subject has been done by Kolmogorov [6], Wiener [7], Kalman [4], Bucy [8], and many others in the last century. We can also mention closely related works by Wald [9], and Robbins and Monroe [10], where the *stochastic approximation* algorithm developed in Ref. 10 may be utilized for parameter estimation.

Stationary and nonstationary time series models such as autoregressive (AR), moving average (MA), mixed autoregressive and moving average (ARMA), autoregressive integrated moving average (ARIMA), autoregressive and moving average with external input (ARMAX), can be translated into state-space models [2,3,11–13], thus benefit from the recursive prediction algorithm. Multivariate time series are especially suitable to state-space representation. For example, Aviv [14] uses state-space models and Kalman filter in demand estimation and inventory control. Bayesian estimation can also exploit the Kalman filtering methodology, as discussed in Refs 15 and 16.

We introduce the general state-space model in the next section, and then focus on linear Gaussian model in the section titled “Linear Gaussian Model.” We describe Kalman filter iterations in the section titled “Kalman Filter for State Estimation.” The

adaptive and nonlinear generalizations follow in the sections titled “Adaptive State Estimation” and “Nonlinear State Estimation,” respectively. The parameter estimation can also be approached by utilizing a Kalman filter, as presented in the section titled “Parameter Estimation.”

STATE-SPACE STRUCTURE

A mathematical model of a dynamic system with multiple inputs and outputs can be constructed as follows. Let x_t be the multidimensional (vector) state of the system, $\mathcal{X}$ be the state-space, u_t be an observable multidimensional input to the system, and y_t be an observable multidimensional output of the system, at time t . Also, let v_t and w_t denote multidimensional random noise processes, at time t . Assume $x_{t+1} = f_t(x_t, u_t, v_t)$, $y_t = g_t(x_t, w_t)$, where f, g are measurable functions at all time. By using this simple model, we try to capture and express the relationships between the state of the system, the input that drives it, and the output of the system. The k -step ahead state, x_{t+k} , depends upon the present state, x_t , as well as the future inputs, such that, $x_{t+k} = f_{t+k-1}(f_{t+k-2}(\dots(f_t(x_t, u_t, v_t))\dots), u_{t+k-1}, v_{t+k-1})$. This recursion is the basis for state transitions from period t to k -step ahead period $t+k$.

LINEAR GAUSSIAN MODEL

In this section, we will consider linear state-space models operating in continuous or discrete time. Let the initial (starting) state be denoted as $x(t_0)$ for the continuous and $x(k_0)$ for the discrete-time process.

Continuous-Time Model. Assume that the state dynamics, or evolution is as follows,

$$\frac{d}{dt}x(t) = A_t x(t) + B_t u(t) + G_t v(t).$$

Also the observed output, or response is given by

$$y(t) = C_t x(t) + w(t),$$

where $x(t), u(t), y(t)$ are finite real vectors, A_t, B_t, C_t, G_t are real matrices with proper dimensions and $t \geq t_0$ is a real number.

The noise processes $\{v(t)\}, \{w(t)\}$ are independent Gaussian random vectors, with zero means and finite variances, conditionally independent of $x(t)$ and $u(t)$. Let $\{v(t)\}$ be a white Gaussian stochastic process with covariance

$$E[v(t)v^T(t-\tau)] = Q(t)\delta(t-\tau),$$

and $\{w(t)\}$ be a white Gaussian stochastic process with covariance

$$E[w(t)w^T(t-\tau)] = R(t)\delta(t-\tau),$$

where $\delta(\cdot)$ is the Kronecker delta function, that is, its value is one when its argument is zero, its value is zero otherwise. Since these stochastic processes are uncorrelated, we have

$$\begin{aligned} E[v(t)w^T(t)] &= E[x(0)v^T(t)] \\ &= E[x(0)w^T(t)] \\ &= E[u(t)v^T(t)] \\ &= E[u(t)w^T(t)] = 0. \end{aligned}$$

Discrete-Time Model. Assume that the state dynamics is given by

$$x(k+1) = A_k x(k) + B_k u(k) + G_k v(k),$$

and the observation equation is

$$y(k) = C_k x(k) + w(k),$$

where $x(k), u(k), y(k)$ are finite real vectors, A_k, B_k, C_k, G_k are real matrices with proper dimensions and $k \geq k_0$ is an integer.

The noise processes $\{v(k)\}, \{w(k)\}$ are independent Gaussian random vectors, with zero means and finite variances, conditionally independent of $x(k)$ and $u(k)$, and temporally uncorrelated, that is, $E[v(k)v^T(j)] = Q(k)\delta_{kj}$, $E[w(k)w^T(j)] = R(k)\delta_{kj}$, where δ_{kj} is the Kronecker delta, that is, its value is one when $k=j$, and zero otherwise.

In these models, the system's evolution can be represented by state transition,

$$x(t|t_0) = \Phi(t, t_0)x_{t_0} + \int_{t_0}^t \Phi(t, s)B(s)u(s) ds,$$

where $\Phi(., .)$ is the state-transition function (a matrix, or a dynamic semigroup operator on the state-space), $x(t_0)$ is the initial state of the system and integral is a summation operator in the Lebesgue sense [17] that operates both in the continuous time and in the discrete time, componentwise.

Note that for linear systems, the initial state is a critical point for the future trajectory of the system. On the other hand, if the system is not linear, then the initial state of the system is not sufficient for the system's behavior, system's trajectories would depend upon other factors as well. Many trajectories (perhaps infinitely many) from the same initial state are possible. There are two essential questions:

- Q1. Is the system *observable*, that is, is it possible to determine the states of the system $\{x(s)|t_0 \leq s < t\}$, from the observations of $y(s)$ and $u(s)$, for $s \in [t_0, t)$?
- Q2. Is the system *controllable*, that is, is it possible to drive the system into a desired state $x(t_f)$, from an initial state $x(t_0)$, by selecting a stream of feasible inputs (stimuli) $\{u(s)|t_0 \leq s \leq t_f\}$, in a finite interval of time $[t_0, t_f]$?
- For the discrete-time system dynamics, we replace t, t_0, t_f by k, k_0, k_f , respectively.

The duality of these questions, as well as the state-space formulation of linear systems for predicting and controlling the system's behavior were explained by many researchers, for one particular approach, see Ref. 5.

The first question is relevant to forecasting, or estimating the states of a linear dynamical system, and can be approached by the Wiener filter [7]. Wiener filter provides the best estimates (in the sense of minimum mean square error [18]) of the Markovian signals $x(t)$, by using a set of observations $\{y(s), s \in [t_0, t]\}$. State estimates, $\hat{x}(s|t)$ may

be obtained for prediction or $\hat{x}(t|t) := \hat{x}(t)$, for filtering when $s > t > t_0$. The Wiener filter is based on a function, $h(t)$, such that its convolution with the past observations, $h \star y$, would generate the state estimator,

$$\hat{x}(t) = \int_0^\infty h(s)y(t-s) ds.$$

The function, $h(t)$ is selected to minimize the expected squared estimation error,

$$E[(x(t) - \hat{x}(t))^2] = E[x^2(t)] - 2E[\hat{x}(t)x(t)] + E[\hat{x}^2(t)].$$

Since $E[\hat{x}^2(t)] = \int_0^\infty h(s) ds \int_0^\infty h(\tau) R_{yy}(t, \tau) d\tau$ and $E[\hat{x}(t)x(t)] = \int_0^\infty h(s) R_{xy}(t, s) ds$, where R_{yy} is the autocorrelation function of the observations $y(t)$ and R_{xy} is the correlation function of $x(t)$ and $y(t)$, then the optimum filter, say h^* satisfies,

$$\int_0^\infty h^*(\tau) R_{yy}(t, \tau) d\tau = R_{xy}(t),$$

which is known as the *Wiener-Hopf equation*, and its solution for h^* yields the best linear estimator for state $x(t)$ [7].

KALMAN FILTER FOR STATE ESTIMATION

The Kalman filter, also known as *Kalman-Bucy filter*, is a sequential estimator for the states of a stationary linear dynamical system and it is based on the Wiener filter, subject to a white Gaussian noise. Without loss of generality, we can set the initial time t_0 to be 0. The usual Kalman filter formulation, such as given in Ref. 19, for a known distribution of the initial state, $x(0)$, is carried on the following simplified state-space equations. Note that, the control component is not included in this model, thus one is concerned only with the state estimation problem.

Continuous Time:

$$\begin{aligned} \frac{d}{dt}x(t) &= A_t x(t) + G_t v(t) \text{ and} \\ y(t) &= C_t x(t) + w(t), \text{ for } t \geq 0. \end{aligned}$$

Discrete Time:

$$\begin{aligned} x(k+1) &= A_k x(k) + G_k v(k) \text{ and} \\ y(k) &= C_k x(k) + w(k), \text{ for } k \geq 0. \end{aligned}$$

The Kalman filter first estimates the state of the system, then updates the estimation process, according to the estimation error that manifests itself in the difference of actual observation and the estimated observation which is based on the state estimation. Hence, these two stages of estimation–correction process repeats itself for the entire forecasting horizon. In our model, noises and states are independent Gaussian random processes with finite second moments. Also let $E[x(0)] = \bar{x}(0)$ and $\text{Var}(x(0)) = P_0$.

Continuous-Time Case

Let $\hat{x}(s|t)$ be the estimate of $x(s)$, given all $y(\tau)$, for $0 \leq \tau \leq t$ and $s > t \geq 0$. Also, let $e(s|t) = x(s) - \hat{x}(s|t)$ be the estimation error, at time s .

Therefore, one must find the linear filter $K(t, \tau)$ such that $\hat{x}(s|t) = \int_0^t K(s, \tau) y(\tau) d\tau$, where $\hat{x}(0|0) = \bar{x}(0)$. Also, the mean squared error, $E[\|e(s|t)\|^2]$ is minimized by this filter, where $\|e(s|t)\|$ denotes the Euclidean norm of the error vector.

If this filter, $K(t, \tau)$, satisfies the Wiener–Hopf equation, then $\hat{x}(s|t)$ will be an unbiased minimum variance estimator of $x(s)$ (for the proof see Ref. 8). Hence, this filter will satisfy,

$$\frac{d}{dt} \hat{x}(t|t) = \int_0^t \frac{\partial}{\partial t} K(t, \tau) y(\tau) d\tau + K(t, t) y(t),$$

and

$$\frac{d}{dt} \hat{x}(t|t) = A_t \hat{x}(t|t) + K(t, t) [y(t) - C_t \hat{x}(t|t)],$$

where $\hat{x}(0|0) = \bar{x}(0)$. The estimation error, $e(t|t) = x(t) - \hat{x}(t|t)$, will be subject to the following evolution,

$$\begin{aligned} \frac{d}{dt} e(t|t) &= [A_t - K(t, t) C_t] e(t|t) + G_t v(t) \\ &\quad - K(t, t) w(t). \end{aligned}$$

Let the covariance of the estimation error be $E[e(t|t)e^T(t|t)] = P(t)$, and $P(0) = P_0$.

In order to obtain the least square error estimator, the estimation error, $e(t|t)$, must be orthogonal to the state estimate, $\hat{x}(t|t)$, that is, $E[e(t|t)\hat{x}(t|\tau)] = 0$, for $t \geq \tau \geq 0$.

Thus, by solving for the above estimation error differential equation, we obtain the evaluation of the error function as follows:

$$\begin{aligned} e(t|t) &= \Psi(t, 0) e(0|0) \\ &\quad - \int_0^t \Psi(t, \tau) [K(\tau, \tau) w(\tau) - G_\tau v(\tau)] d\tau, \end{aligned}$$

where $\Psi(\cdot, \cdot)$ denotes the transition function for e . Therefore,

$$\begin{aligned} P(t) &= \Psi(t, 0) E[e(0|0)e^T(0|0)] \Psi^T(t, 0) \\ &\quad - \int_0^t \int_0^t \Psi(t, \tau) [K(\tau, \tau) \\ &\quad \times E[w(\tau)w^T(s)] K^T(s, s)] \Psi^T(t, s) ds d\tau \\ &\quad + \int_0^t \int_0^t \Psi(t, \tau) G_\tau E[v(\tau)v^T(s)] G_s^T \\ &\quad \times \Psi^T(t, s) ds d\tau. \end{aligned}$$

By taking the time derivative of the above function, we have the following Riccati equation for the covariance of the estimation error,

$$\begin{aligned} \frac{d}{dt} P(t) &= G_t Q(t) G_t^T + A_t P(t) + P(t) A_t^T \\ &\quad - P(t) C_t^T R^{-1}(t) C_t P(t), \end{aligned}$$

where, $P(t) C_t^T = E[e(t|t)e^T(t|t)] C_t^T = K(t, t) R(t)$. Hence, this yields $K(t, t) = P(t) C_t^T R^{-1}(t)$.

In summary, the Kalman filter is defined by the following equations, for $t \geq 0$:

$$\frac{d}{dt} \hat{x}(t|t) = A_t \hat{x}(t|t) + K(t, t) [y(t) - C_t \hat{x}(t|t)],$$

where $\hat{x}(0|0) = \bar{x}(0)$,

$$\begin{aligned} K(t, t) &= P(t) C_t^T R^{-1}(t), \\ \frac{d}{dt} P(t) &= A_t P(t) + P(t) A_t^T + G_t Q(t) G_t^T \\ &\quad - P(t) C_t^T R^{-1}(t) C_t P(t). \end{aligned}$$

The forecasting of future states can be done by $\hat{x}(s|t) = \Phi(s, t) \hat{x}(t|t)$, for $s > t > 0$ and by using the state-transition function $\Phi(\cdot, \cdot)$.

Discrete-Time Case

Let $\hat{x}(k|m) = E[x(k)|y(0), y(1), \dots, y(m)]$ be the state estimator and $e(k|m) = x(k) - \hat{x}(k|m)$ be the estimation error, for $k \geq m$. The best estimator of states has the minimum mean square estimation error property, which is obtained by the orthogonal projection of the state estimator on the observations, with the following Kalman recursions.

$$\begin{aligned}\hat{x}(k|k) &= \hat{x}(k|k-1) + P(k-1)C_k^T \\ &\quad \times [C_k P(k-1)C_k^T + R(k)]^{-1}(y(k) \\ &\quad - C_k \hat{x}(k|k-1)), \\ P(k|k) &= P(k-1) - P(k-1)C_k^T [C_k P(k-1)C_k^T \\ &\quad + R(k)]^{-1} C_k P(k-1),\end{aligned}$$

where $P(k|k) = E[e(k|k)e^T(k|k)]$. Also, $\hat{x}(k+1|k) = A_k \hat{x}(k|k)$, that is,

$$\begin{aligned}\hat{x}(k+1|k) &= A_k \hat{x}(k|k-1) + A_k P(k-1)C_k^T \\ &\quad \times [C_k P(k-1)C_k^T + R(k)]^{-1}(y(k) \\ &\quad - C_k \hat{x}(k|k-1)), \quad \text{and} \\ e(k+1|k) &= A_k e(k|k-1) + A_k P(k-1)C_k^T \\ &\quad \times [C_k P(k-1)C_k^T + R(k)]^{-1}(y(k) \\ &\quad - C_k \hat{x}(k|k-1) - G_k v(k)).\end{aligned}$$

The estimation error covariance, $P(k) = E[e(k+1|k)e^T(k+1|k)]$, that is,

$$\begin{aligned}P(k) &= A_k P(k-1)A_k^T - A_k P(k-1)C_k^T \\ &\quad \times [C_k P(k-1)C_k^T + R(k)]^{-1} C_k P(k-1) \\ &\quad \times A_k^T + G_k Q(k)G_k^T,\end{aligned}$$

where $\hat{x}(0|0) = E[x(0)]$ and $P(0) = \text{Var}(x(0))$.

This discrete-time Kalman filter is a minimum variance and minimum mean square error sequential estimator of the state.

We can construct a predictor, based on this discrete Kalman filter, to forecast a distant future, $\hat{x}(n|k) = \prod_{j=k, \dots, n} A_j \hat{x}(k|k)$, for $n > k > 0$.

In this approach, predictor-corrector structure of the Kalman filter is generating an *innovation* sequence, $y(k) - \hat{y}(k)$, which is a zero-mean and independent stochastic

process (based on the maximum likelihood estimation, or, orthogonal projection method). There are other approaches for optimal state estimators, such as recursive Bayesian estimators, but when the system is linear and the noise structure is independent Gaussian, these methods converge to the Kalman filter [8].

ADAPTIVE STATE ESTIMATION

When there are uncertainties in the system parameters, Kalman filter cannot provide the state estimation. We can approach to those cases with a Bayesian construct [15,16,20]. Let the parameter vector θ is subject to uncertainty, where the linear system dynamics are as before.

For continuous time: $\frac{d}{dt}x(t) = A(t, \theta)x(t) + G(t, \theta)v(t)$ and $y(t) = C(t, \theta)x(t) + w(t)$, where $v(t)$ and $w(t)$ are independent zero-mean white Gaussian random vectors with $Q(t)\delta(t)$ and $R(t)\delta(t)$ covariances, respectively. The initial state is an independent Gaussian random vector with mean $\hat{x}(0|0, \theta)$ and variance $P(0|0, \theta)$.

The system evolution is subject to its unknown parameter vector, $\theta \in \Omega$, with its prior probability density $f(\theta)$. On the basis of the observation data, $Y_t = \{y(s)|0 \leq s \leq t\}$, the minimum mean square estimate of the state, $\hat{x}(t|t) = \int_{\Omega} \hat{x}(t|t, \theta) f(\theta|Y_t) d\theta$, where $\hat{x}(t|t) = E[x(t)|Y_t]$, $\hat{x}(t|t, \theta) = E[x(t)|Y_t, \theta]$, over the sample space of the parameter, Ω .

The posterior probability density of the parameter, based on the observations, would be as follows:

$$\begin{aligned}f(\theta|Y_t) &= f(\theta) \exp \left(- \int_0^t \hat{x}(\tau|\tau, \theta) C^T(\tau, \theta) \right. \\ &\quad \times R^{-1}(\tau) y(\tau) d\tau \\ &\quad \left. - \frac{1}{2} \int_0^t \|C(\tau, \theta) \hat{x}(\tau|\tau, \theta)\|^2 R^{-1}(\tau) d\tau \right) \\ &\quad \times \exp \left(- \int_0^t \hat{y}^T(\tau|\tau) R^{-1}(\tau) y(\tau) d\tau \right. \\ &\quad \left. - \frac{1}{2} \int_0^t \|\hat{y}(\tau|\tau)\|^2 R^{-1}(\tau) d\tau \right),\end{aligned}$$

where $\hat{y}(\tau|\tau) = \int_{\Omega} C(\tau, \theta) \hat{x}(\tau|\tau) f(\theta|Y_t) d\theta$.

The conditional covariance of the state estimation error would be,

$$P(t) = \int_{\Omega} P(t|t, \theta) [\hat{x}(t|t, \theta) - \hat{x}(t|t)] [\hat{x}(t|t, \theta) - \hat{x}(t|t)]^T f(\theta|Y_t) d\theta,$$

where $P(t|t, \theta) = E[(x(t) - \hat{x}(t|t, \theta))(x(t) - \hat{x}(t|t, \theta))^T | Y_t, \theta]$, for all $\theta \in \Omega$.

The same procedure is also suitable for the discrete-time estimations, as follows.

For discrete time: $x(k+1) = A(k, \theta)x(k) + v(k)$ and $y(k) = C(k, \theta)x(k) + w(k)$, where $v(k)$, $w(k)$ are independent zero-mean Gaussian

vectors with covariances $Q(k)\delta_{kj}$ and $R(k)\delta_{kj}$, respectively.

The initial state is an independent random vector with mean $\hat{x}(0|0, \theta)$ and covariance $P(0|0, \theta)$. Let the unknown parameter has a prior probability density $f(\theta)$. Hence, based on a realization of past observations, $Y_k = \{y(j) | j = 1, 2, \dots, k\}$, the minimum mean square error state estimate would be $\hat{x}(k|k) = \int_{\Omega} \hat{x}(k|k, \theta) f(\theta|Y_k) d\theta$, where $\hat{x}(k|k) = E[x(k)|Y_k]$ and $\hat{x}(k|k, \theta) = E[x(k)|Y_k, \theta]$.

The posterior probability of the parameter, based on the observation data,

$$f(\theta|Y_k) = \frac{\left[|P_z(k|k-1, \theta)|^{-\frac{1}{2}} \exp\left(-\frac{1}{2} \|y(k) - C(k, \theta)\hat{x}(k|k-1, \theta)\|^2 P_z^{-1}(k|k-1, \theta)\right) f(\theta|Y_{k-1}) \right]}{\left[\int_{\Omega} f(\theta|Y_k) |P_z(k|k-1, \theta)|^{-\frac{1}{2}} \exp\left(-\frac{1}{2} \|y(k) - C(k, \theta)\hat{x}(k|k-1, \theta)\|^2 P_z^{-1}(k|k-1, \theta)\right) d\theta \right]},$$

where $y(k) - C(k, \theta)\hat{x}(k|k-1, \theta)$ is the conditional white noise process with covariance $P_z(k|k-1, \theta) = C(k, \theta)P(k|k-1, \theta)C^T(k, \theta) + R(k)$.

Moreover, the state estimation error covariance would be $P(k|Y_k) = \int_{\Omega} (P(k|k, \theta) + [\hat{x}(k|k, \theta) - \hat{x}(k|k)][\hat{x}(k|k, \theta) - \hat{x}(k|k)]^T) f(\theta|Y_k) d\theta$.

NONLINEAR STATE ESTIMATION

The state estimation for nonlinear systems is very difficult, to say the least, unlike the linear systems. Under suitable conditions, a linearization could be an approximation of a nonlinear system's representation, then we may employ the Kalman filter approach, but always be mindful of the divergence of the approximation from the actual system.

Let us modify our state-space model for the nonlinear structure, as follows:

1. $\frac{d}{dt}x(t) = g(x, t) + v(t)$ and $y(t) = h(x, t) + w(t)$, for continuous time,
2. $x(k+1) = g(x, k) + v(k)$ and $y(k) = h(x, k) + w(k)$, for discrete time,

where x, y are state and output (observation) vectors, also let g, h are differentiable vector functions, representing the system dynamics (evolution), and v, w are zero-mean independent Gaussian random vectors with time-varying covariances, Q and R , respectively.

1. *Continuous Time.* At time t , the first-order Taylor series expansion for g and h , around the estimated state, $\hat{x}$, would be as follows:

$$g(x, t) = g(\hat{x}, t) + A(\hat{x}, t)(x - \hat{x}) + \epsilon$$

$$\text{and } h(x, t) = h(\hat{x}, t) + C(\hat{x}, t)(x - \hat{x}) + \varepsilon,$$

where ϵ, ε are the approximation errors, such that

$$A(\hat{x}, t) = \begin{pmatrix} \frac{\partial g_1}{\partial x_1} & \dots & \frac{\partial g_1}{\partial x_n} \\ \vdots & & \vdots \\ \frac{\partial g_n}{\partial x_1} & \dots & \frac{\partial g_n}{\partial x_n} \end{pmatrix},$$

$$C(\hat{x}, t) = \begin{pmatrix} \frac{\partial h_1}{\partial x_1} & \dots & \frac{\partial h_1}{\partial x_n} \\ \vdots & & \vdots \\ \frac{\partial h_m}{\partial x_1} & \dots & \frac{\partial h_m}{\partial x_n} \end{pmatrix},$$

$$\text{and } H_i(\hat{x}, t) = \begin{pmatrix} \frac{\partial^2 h_i}{\partial x_1^2} & \dots & \frac{\partial^2 h_i}{\partial x_1 \partial x_n} \\ \vdots & & \vdots \\ \frac{\partial^2 h_i}{\partial x_n \partial x_1} & \dots & \frac{\partial^2 h_i}{\partial x_n^2} \end{pmatrix},$$

for $i = 1, \dots, m$.

Here, the functions g and h are evaluated at $\hat{x}(t)$.

Then the extended Kalman filter for the state estimation would be as follows [21]:

$$\begin{aligned} \frac{d}{dt}\hat{x}(t) &= g(\hat{x}, t) + \hat{P}(t)C(\hat{x}, t)R^{-1}(t) \\ &\quad \times [y(t) - h(\hat{x}, t)], \\ \frac{d}{dt}\hat{P}(t) &= \hat{P}(t)A^T(\hat{x}, t)\hat{P}(t) + Q(t) - \hat{P}(t) \\ &\quad \times C^T(\hat{x}, t)R^{-1}(t)C(\hat{x}, t)\hat{P}(t) \\ &\quad + \sum_{i=1, \dots, m} \hat{P}(t)H_i(\hat{x}, t)I[i]R^{-1}(t) \\ &\quad \times [y(t) - h(\hat{x}, t)], \end{aligned}$$

where $I[i]$ is the i th row of the identity matrix I .

2. *Discrete Time.* The extended Kalman filter construct can be carried out as follows,

$$\begin{aligned} \hat{x}(k+1|k+1) &= g(\hat{x}(k|k)) + \hat{P}(k+1|k+1) \\ &\quad \times C^T(\hat{x}, k+1)R^{-1}(k+1) \\ &\quad \times [y(k+1) - C(\hat{x}, k+1) \\ &\quad \times g(\hat{x}(k|k))], \\ \hat{P}(k+1|k+1) &= [R(k) + C^T(\hat{x}, k+1) \\ &\quad \times P(k+1|k)C(\hat{x}, k+1)]^{-1} \\ &\quad \times \hat{P}(k+1|k), \\ \hat{P}(k+1|k) &= A(\hat{x}, k)\hat{P}(k|k)A^T(\hat{x}, k) \\ &\quad + Q(k). \end{aligned}$$

There are methods to improve the convergence of extended Kalman filter [19,22] and apply these improved extended Kalman filters to adaptive controller design [23,24].

The linearization could also be made around a reference (nominal) trajectory, $\bar{x}(t)$, with a given $\bar{x}(0)$, such that $\frac{d}{dt}\bar{x}(t) = g(\bar{x}(t), t)$, for $t \geq 0$.

Also, let $\Delta x(t) = x(t) - \bar{x}(t)$ be a Gaussian perturbation from the reference trajectory. Hence, $\frac{d\Delta x(t)}{dt} = g(x(t), t) - g(\bar{x}(t), t) + v(t)$. Therefore, the first-order Taylor series approximation would be, $g(x(t), t) - g(\bar{x}(t), t) = A(\bar{x}(0), t)\Delta x(t)$, where $A(\bar{x}(0), t)$

is evaluated along the reference trajectory, $\frac{d\Delta x(t)}{dt} = A(\bar{x}(0), t)\Delta x(t) + v(t)$. Hence, the Kalman filter approach could be used with $\hat{x}(0) = \bar{x}(0)$.

PARAMETER ESTIMATION

We can estimate the parameter, together with the state of a system, by using the above constructed extended Kalman filter structure. Let the state vector x be augmented with the parameter vector θ , such that,

$$z(t) = \begin{pmatrix} x(t) \\ \theta(t) \end{pmatrix} \text{ and } V(t) = \begin{pmatrix} v(t) \\ 0 \end{pmatrix}.$$

1. $\frac{d}{dt}z(t) = g(z, t) + V(t)$ and $y(t) = h(z, t) + w(t)$, for continuous time,
2. $z(t+1) = g(z, k) + V(k)$ and $y(k) = h(z, k) + w(k)$, for discrete time.

A linearization is obtained by the first-order Taylor series expansion, around the augmented state estimate $\hat{z}$. Without loss of generality, in discrete time a linearized Kalman filter that generates state and parameter estimation would be as follows,

$$\begin{aligned} \hat{z}(k+1) &= \hat{z}(k+1|k) + K(k+1) \\ &\quad \times [y(k+1) - h(\hat{z}(k+1|k), k)], \end{aligned}$$

with $\hat{z}(0|0) = z(0)$,

$$h(\hat{z}(k+1|k), k) = C(k, \hat{\theta}_k)\hat{x}(k+1|k),$$

$$\hat{z}(k+1|k) = F(k)\hat{z}(k),$$

$$K(k+1) = P(k+1|k+1)G(k)R^{-1}(k),$$

$$\begin{aligned} P(k+1|k+1) &= P(k+1|k) - P(k+1|k)G(k) \\ &\quad \times [G^T(k)P(k+1|k)G(k) \\ &\quad + R(k)]^{-1}G^T(k)P(k+1|k), \end{aligned}$$

$$\begin{aligned} P(k+1|k) &= F(k)P(k|k)F^T(k) \\ &\quad + Q(k)G(k)G^T(k), \end{aligned}$$

where F, G, R, Q are appropriate matrices for the augmented state-parameter vector z , and θ_0 is a priori information about the parameter.

These methods provide sequential estimation of the state and the parameter for stationary and linear, or linearized systems yet they suffer immensely in real-time computations. Divergency is a common problem for linearized models [24], that is the success of estimation depends upon a very good initial point for the nominal trajectory and persistent corrections for very well-behaved systems.

CONCLUSION

The Kalman Filter is a recursive state estimator for a linear system, subject to a random noise. It has many technological applications in diverse engineering fields, which are implemented by digital systems. Thus the discrete version of the Kalman filter is much more common.

The Kalman filter has a sequence of two phases; it predicts the state of a linear system then compares it with the observations and adjusts the filter gain. Henceforth, this recursive instrument for estimating the states and refining the estimation process has been utilized in adaptive controllers, particularly in the linear-quadratic-Gaussian controllers, where a linear system is subject to an independent Gaussian random noise, and the controller minimizes a quadratic error function (performance measure). When the system structure has nonlinearities, the filter is not appropriate for state estimation. For those cases, an extended Kalman filter (EKF) is constructed, where a Taylor series expansion around the presently estimated state, or around a nominal state value, linearizes the system dynamics.

There are divergence problems in the Kalman filter implementations, and also actual computations suffer from the curse of the dimensionality. Thus, persistent adjustments are needed and the Kalman filter begs for clever tricks to expedite the filter gain computations.

FORMULATING GOOD MILP MODELS

JOHN N. HOOKER
Carnegie Mellon University,
Pittsburgh, Pennsylvania

Mixed integer/linear programming (MILP) provides a highly developed technology for solving a wide variety of optimization problems with continuous and discrete variables. To harness this technology, however, one must know how to formulate a given problem as an MILP model. In many cases, it is not enough to simply write a correct model. One must also write a “good” model, meaning that the formulation is amenable to fast solution. A poor formulation can require, by orders of magnitude, more solution time than a good one.

MILP problem formulation is generally regarded as an art rather than a science, but it need not be unprincipled. An underlying theory tells us precisely which problems can be given in an MILP formulation, and this in turn leads to useful guidelines for writing good models.

The guidelines are based on the fact that MILP formulations involve two modeling ideas: knapsack constraints and choices between discrete alternatives (disjunctions). By identifying these two elements in a given problem, one can obtain practical MILP formulations in a reasonably systematic way. The resulting models incorporate many of the “tricks” that one might otherwise learn only through familiarity with the folklore of modeling.

The characteristics of a good model have never been precisely defined, but in many cases, it is useful to have a “tight” continuous relaxation. The relaxation is important because its solution provides a bound on the optimal value of the original problem. A bound from a tight relaxation is closer to the optimal value and can accelerate solution,

because all general-purpose MILP solvers make essential use of bounds to prune the search tree.

BASIC DEFINITIONS

An MILP problem consists of linear inequality constraints and a linear objective function. At least some of the variables must take integer values, while the remaining variables are continuous. Such a problem can be written in the form

$$\begin{aligned} \min \text{ (or max) } & cx \\ Ax & \geq b \\ x & \in \mathbb{R}^n, \quad x_j \in \mathbb{Z} \quad \text{for } j \in J. \end{aligned} \quad \begin{matrix} (a) \\ (b) \end{matrix} \quad (1)$$

where $x = (x_1, \dots, x_n)$ and A is an $m \times n$ matrix. Variables x_j for $j \in J$ must take integer values. A value of x is *feasible* for Equation (1) if it satisfies the constraints (a) and (b), and the *feasible set* is the set of feasible values. The objective is to find a feasible x that minimizes (or maximizes) cx .

The *continuous relaxation* of Equation (1) is obtained by dropping the integrality condition on x_j for $j \in J$. The continuous relaxation is generally much easier to solve than Equation (1), because it is a linear programming problem. Its optimal value is a lower bound on the optimal value of Equation (1) if the objective is to minimize, and an upper bound if the objective is to maximize.

KNAPSACK MODELING

Mixed integer formulations frequently involve counting ideas that can be expressed as *knapsack inequalities*. For present purposes, we can define a knapsack inequality to be one of the form $\sum_j a_j x_j \leq \beta$, or $ax \leq \beta$ for short, where some (or all) of the variables x_j may be restricted to integer values. We also regard $ax \geq \beta$ as a knapsack inequality.

Knapsack Problems

The term *knapsack inequality* derives from the fact that the *integer knapsack problem* can be formulated with such an inequality. The problem is to pack a knapsack with items that have the greatest possible value, while not exceeding a maximum weight β . There are n types of items. Each item of type j has weight a_j and adds value c_j . If x_j is the number of items of type j put into the knapsack, the problem can be written as

$$\begin{aligned} \max \quad & cx \\ ax \leq & \beta \\ x_j \in \mathbb{Z}, \quad & \text{all } j. \end{aligned} \quad (2)$$

This is an MILP model because it has the form of Equation (1).

A wide variety of modeling situations involve this same basic idea. A classic example is the capital budgeting problem, in which the objective is to allocate a limited amount of capital to projects so as to maximize revenue. Here, β is the amount of capital available. There are n types of projects, and each project j has initial cost a_j and earns revenue c_j . Variable x_j represents the number of projects of type j that are funded.

Typically, an MILP model contains many knapsack constraints. There may also be pure linear constraints in which all the variables are continuous. This article focuses on modeling ideas that require integer variables, while the article on **An Introduction to Linear Programming** discusses purely linear modeling.

Example: Freight Transport

A product can be manufactured at several plants, from which it can be shipped to n customers (Fig. 1). Each customer j requires a quantity D_j of the product, and each plant i can manufacture at most C_i . The product must be transported in vehicles, which have capacity K . The cost of sending a vehicle along the route from factory i and to customer j is c_{ij} , regardless of how much cargo it carries. The objective is to assign vehicles to routes to minimize cost while meeting customer demand.

The movement of product from the plants to customers is described by a standard network flow model, which is purely linear. If x_{ij} is the quantity shipped from plant i to customer j , the constraints are

$$\begin{aligned} \sum_j x_{ij} &\leq C_i, \quad \text{all } i, \quad (a) \\ \sum_i x_{ij} &= D_j, \quad \text{all } j. \quad (b) \end{aligned} \quad (3)$$

Constraint (a) ensure that plant capacity is not exceeded, and constraint (b) meet customer demand. The vehicles assigned to each route must have enough capacity to carry the flow x_{ij} along that route. If y_{ij} is the number of vehicles assigned to the route from i to j , this condition is captured by the knapsack inequalities

$$Ky_{ij} \geq x_{ij}, \quad \text{all } i, j, \quad (4)$$

where y_{ij} takes integer values. These are knapsack inequalities because they can be written as $x_{ij} - Ky_{ij} \leq 0$. The objective is to minimize cost

$$\min \sum_{ij} c_{ij} y_{ij}. \quad (5)$$

The MILP model consists of Equations (3)–(5), plus the condition that $x_{ij} \geq 0$ and $y_{ij} \in \mathbb{Z}$ for all i, j .

A variation of this problem allows several types of vehicles to be used. A vehicle of type t has capacity K_t and costs c_{ijt} to operate on the route from i to j . Then if y_{ijt} is the number of vehicles of type t traveling from i to j , the knapsack constraint (4) becomes

$$\sum_t K_t y_{ijt} \geq x_{ij}, \quad \text{all } i, j$$

and the objective Equation (5) becomes

$$\min \sum_{ijt} c_{ijt} y_{ijt}.$$

Figure 1. A freight transport problem.

Set Packing, Set Covering, and Set Partitioning

Special cases of knapsack inequalities occur in set packing, set covering, and set partitioning problems. The *set packing* problem begins with a collection of finite sets S_j for $j = 1, \dots, n$ that may partially overlap. It seeks a largest subcollection of sets that are pairwise disjoint.

Suppose, for example, that there are n surgeries to be performed, and the objective is to perform as many as possible this morning. Surgery j requires a specific set S_j of surgeons and other personnel. Because the surgeries must proceed in parallel, no two surgeries with overlapping personnel can be performed. This is a set packing problem.

The set packing problem can be formulated with 0–1 knapsack inequalities. Let $A_{ij} = 1$ when item i belongs to set S_j , and $A_{ij} = 0$ otherwise. Let variable $x_j = 1$ when set j is selected. The knapsack inequality $\sum_{j=1}^n A_{ij}x_j \leq 1$ prevents the selection of more than one set containing item i . Thus the system $Ax \leq e$ of knapsack inequalities, where e is a vector of ones, prevents the selection of any two overlapping sets. The objective is to maximize $\sum_{j=1}^n x_j$ subject to $Ax \leq e$ and $x \in \{0, 1\}^n$, which is an MILP problem.

The *set covering* problem likewise begins with a collection of sets S_j but seeks the minimum subcollection that contains all the elements in the union of the sets. For example, one may wish to buy a minimum collection of songbooks that contains all the songs that appear in at least one book. Here, S_j is the set of songs in book j .

If A_{ij} and x_j are as before, the knapsack inequality $\sum_{j=1}^n A_{ij}x_j \geq 1$ ensures that item i is covered. The set covering problem is to

minimize $\sum_{j=1}^n x_j$ subject to $Ax \geq e$ and $x \in \{0, 1\}^n$. The objective function in this or the set packing problem can be generalized to cx by attaching a weight c_j to each set S_j , to represent the cost or benefit of selecting S_j .

The *set partitioning* problem seeks a subcollection of sets such that each element is contained in exactly one of the sets selected. The constraints are therefore $Ax = e$, which are a combination of the knapsack constraints $Ax \leq e$ and $Ax \geq e$. The problem is to minimize or maximize cx subject to these constraints.

Example: Airline Crew Rostering

An important practical example of set partitioning is the airline crew rostering problem. Crews must be assigned to sequences of flight legs, while observing complicated work rules. For example, there are restrictions on the number of flight legs a crew may staff in one assignment, the total duration of the assignment, the layover time between flight legs, and the locations of the origin and destination.

Let S_j be a set of flight legs that can be assigned to a single crew, where j indexes all possible such sets. There may be millions of sets S_j and therefore millions of variables x_j . A set S_j is selected ($x_j = 1$) when it is assigned to a crew, incurring cost c_j . This is a partitioning problem because each flight leg must be staffed by exactly one crew and must therefore appear in exactly one selected S_j .

There are ways to formulate the problem with a much smaller model that explicitly represents the work rules with constraints. Yet, the set partitioning model has the advantage that it can be solved by *branch-and-price* methods. These methods solve

the continuous relaxation by *column generation*; that is, by adding variables (and the associated columns of A) to the problem only when they can improve the solution. Typically, only a tiny fraction of the columns are generated. This is an instance in which a large model is “better” than a small one in the sense that it permits faster solution.

Clique Inequalities

A collection of set packing constraints in a model can sometimes be replaced or supplemented by a *clique inequality*, which substantially tightens the relaxation. For example, the 0–1 inequalities

$$\begin{aligned} x_1 + x_2 &\leq 1, \\ x_1 + x_3 &\leq 1, \\ x_2 + x_3 &\leq 1. \end{aligned} \quad (6)$$

are equivalent to the clique inequality $x_1 + x_2 + x_3 \leq 1$. One can see that the clique inequality provides a tighter relaxation from the fact that $x_1 = x_2 = x_3 = 1/2$ violates it but satisfies Equation (6). It should therefore replace Equation (6) in the model.

To generalize this idea, define a graph whose vertices j correspond to 0–1 variables x_j . The graph contains an edge (i, j) whenever $x_i + x_j \leq 1$ is implied by a constraint in the model. If the induced subgraph on some subset C of vertices is a clique, then $\sum_{j \in C} x_j \leq 1$ is a valid inequality and can be added to the model.

Logical Conditions

Logical conditions on 0–1 variables can be formulated as knapsack inequalities that are similar to set covering constraints. Suppose, for example, that either plants 2 and 3 must be built, or else plant 1 must not be built. For the moment, regard x_j as a Boolean variable that is true when plant j is built, and false otherwise. The condition can be written as

$$\neg x_1 \vee x_2 \vee x_3, \quad (7)$$

where $\vee$ means “or” and $\neg$ means “not.” Such a condition is a *logical clause*, meaning that it is a disjunction of *literals* (Boolean variables or their negations). Because the clause states

that at least one of the literals must be true, it can be written as an inequality $(1 - x_1) + x_2 + x_3 \geq 1$ by viewing x_j as true when $x_j = 1$ and false when $x_j = 0$. This is equivalent to the knapsack inequality $-x_1 + x_2 + x_3 \geq 0$.

Any logical condition built from “and,” “or,” “not,” and “if” can be converted to a set of clauses and given an MILP model on that basis. One need to observe only three equivalences:

- $A \Rightarrow B$ (i.e., “ A implies B ,” or “ B if A ”) is equivalent to $\neg A \vee B$;
- $\neg(A \wedge B)$ is equivalent to $\neg A \vee \neg B$ (De Morgan’s Law), where $\wedge$ means “and;”
- $A \vee (B \wedge C)$ is equivalent to $(A \vee B) \wedge (A \vee C)$, a form of distribution.

Consider, for example, the condition, “If plants 1 and 2 are built, then plants 3 and 4 must be built.” It can be written as

$$(x_1 \wedge x_2) \Rightarrow (x_3 \wedge x_4).$$

The implication is first eliminated to obtain $\neg(x_1 \wedge x_2) \vee (x_3 \wedge x_4)$. The negation is then brought inside using De Morgan’s Law, resulting in the expression $\neg x_1 \vee \neg x_2 \vee (x_3 \wedge x_4)$. The conjunction is now distributed as

$$(\neg x_1 \vee \neg x_2 \vee x_3) \wedge (\neg x_1 \vee \neg x_2 \vee x_4).$$

This conjunction of two clauses can be written as two knapsack constraints

$$\begin{aligned} -x_1 - x_2 + x_3 &\geq -1, \\ -x_1 - x_2 + x_4 &\geq -1. \end{aligned}$$

A model can sometimes be further tightened by generating *resolvents* of the clauses. Suppose, for example, that a model contains clauses $x_1 \vee x_2$, $\neg x_1 \vee \neg x_3$. Because exactly one variable (x_1) occurs in the two clauses with different signs, one can infer the resolvent $x_2 \vee \neg x_3$, which contains all the literals in either clause except x_1 and $\neg x_1$. The resolvent is converted to knapsack form and added to the MILP model. The process can be repeated as desired, and clauses implied by others (if any) can be dropped.

Figure 2. (a) Feasible set of a fixed-charge problem, consisting of the union of polyhedra P_1 (heavy vertical line) and P_2 (shaded area). (b) Feasible set $P_1 \cup P'_2$ of the same problem with the bound $x_1 \leq U$, where P'_2 is the darker shaded area. The convex hull of the feasible set is the entire shaded area.

MILP REPRESENTABILITY

Knapsack-based modeling is useful but harnesses only a fraction of MILP modeling capability. The full resources of MILP modeling appear when one introduces auxiliary 0–1 variables to represent discrete alternatives. A choice among alternatives can be represented by a disjunction in which each term describes one of the alternatives. If each term is a system of knapsack inequalities, the problem has an MILP model, provided the systems satisfy a fairly innocuous technical condition. In fact, the problem has an MILP model *if and only if* it can be written as such a disjunction of knapsack systems.

Example: Fixed-Charge Function

A simple fixed-charge problem illustrates disjunctive modeling. Suppose the cost x_2 of manufacturing quantity x_1 of some product is to be minimized. The cost is zero when $x_1 = 0$ and is $f + cx_1$ otherwise, where f is the fixed cost and c the unit variable cost.

The problem can be viewed as minimizing x_2 subject to $(x_1, x_2) \in S$, where S is the set

depicted in Fig. 2a. There are two discrete alternatives: the cost is zero or the cost is a fixed cost plus a variable cost. They are captured by the disjunctive formulation

$$\begin{aligned} \min x_2 \\ \left(\begin{array}{l} x_2 \geq 0 \\ x_1 = 0 \end{array} \right) \vee \left(\begin{array}{l} x_2 \geq cx_1 + f \\ x_1 \geq 0 \end{array} \right). \end{aligned} \quad (8)$$

The disjuncts define two polyhedra P_1 and P_2 , respectively, illustrated in the figure. In general, there would be additional constraints in the problem, but the focus here is on the fixed-charge formulation.

It is impossible to write an MILP model for the disjunction in Equation (8) because it fails the technical condition mentioned earlier. The condition is that the polyhedra defined by the disjunctions (ignoring the integrality condition) must have the same *recession cone*. The recession cone is the set of directions in which one can go forever without leaving the polyhedron. That is, the recession cone of a polyhedron P is the set of vectors r such that for any $x \in P$, $x + \alpha r \in P$ for all $\alpha \geq 0$. If the polyhedron is bounded, its recession cone is the origin.

The recession cone of P_1 in the example is P_1 itself (Fig. 2a), and the recession cone of P_2 is the set of all vectors (x_1, x_2) with $x_2 \geq cx_1 \geq 0$. However, if an upper bound U is placed on x_1 , the problem becomes

$$\begin{aligned} \min x_2 \\ \left(\begin{array}{l} x_1 = 0 \\ x_2 \geq 0 \end{array} \right) \vee \left(\begin{array}{l} x_2 \geq cx_1 + f \\ 0 \leq x_1 \leq U \end{array} \right). \end{aligned} \quad (9)$$

The recession cone of each of the resulting polyhedra P_1, P'_2 (Fig. 2b) is the same (namely, P_1), and the problem is therefore MILP representable. In fact, it will be shown that the problem has the following MILP model:

$$\begin{aligned} \min x_2 \\ 0 \leq x_1 \leq U\delta, \quad x_2 \geq f\delta + cx_1, \quad \delta \in \{0, 1\}. \end{aligned} \quad (10)$$

which can be simplified to

$$\begin{aligned} \min f\delta + cx_1 \\ 0 \leq x_1 \leq U\delta, \quad \delta \in \{0, 1\} \end{aligned} \quad (11)$$

The 0–1 variable δ encodes whether the quantity produced is zero or positive, in the former case ($\delta = 0$) forcing $x_1 = 0$, and in the latter case, incurring the fixed charge f .

The Representability Theorem

A problem is *MILP representable* if there is some MILP model for it. To make this more precise, suppose one wishes to model an optimization problem $\mathcal{O}$, which can in general be conceived as the problem of minimizing some variable x_j subject to $x \in S$, where $x = (x_1, \dots, x_n)$. Any objective function $f(x)$ can be accommodated by adding variable x_j and constraint $x_j \geq f(x)$ to S , and minimizing or maximizing x_j .

Consider an MILP model $\mathcal{M}$ that minimizes x_j subject to constraints that contain the variables $x_1, \dots, x_n$ (some of which may be restricted to integers), possibly along with auxiliary continuous variables $y_1, \dots, y_m$ and 0–1 variables $\delta_1, \dots, \delta_k$. Model $\mathcal{M}$ represents problem $\mathcal{O}$ if the projection of $\mathcal{M}$'s feasible set onto x is S ; that is, $x \in S$ if and only if (x, y, δ) is feasible in $\mathcal{M}$ for some y, δ . This

means that one can solve $\mathcal{O}$ by solving $\mathcal{M}$, because if (x, y, δ) is an optimal solution of $\mathcal{M}$, then x is an optimal solution of $\mathcal{O}$.

MILP representability is completely characterized by the following theorem, which is proved in Refs 1 and 2. (Technically, the proof assumes that A, c consist of rational data.)

Theorem 1. *An optimization problem that minimizes x_j subject to $x \in S$ is MILP representable if and only if S is the feasible set of some constraint of the form*

$$\begin{aligned} \bigvee_{k \in K} (A^k x \geq b^k), \\ x \in \mathbb{R}^n, \quad x_j \in \mathbb{Z} \quad \text{for } j \in J, \end{aligned} \quad (12)$$

where K is finite and the polyhedra $\{x \mid A^k x \geq b^k\}$ for $k \in K$ have the same recession cone.

Thus, an optimization problem has an MILP model if and only if its feasible set can be described by a disjunction of knapsack systems that define polyhedra with the same recession cone.

If it is difficult to identify the recession cones, one can always ensure that they are the same by placing fixed lower and upper bounds on all the variables—bounds wide enough so as not to be violated by any reasonable solution. This results in bounded polyhedra for every disjunct, so that every recession cone is the origin.

Conversion to an MILP Model

There remains the question as to how to convert the disjunctive problem Equation (12) into an MILP model. There are two standard ways: a big- M formulation and a convex hull formulation. Both require 0–1 auxiliary variables. The convex hull formulation is generally tighter, but at the cost of introducing continuous auxiliary variables as well. First, the big- M formulation.

Theorem 2. *If an optimization problem satisfies the conditions of Theorem 1, it is represented by the big- M formulation*

$$\begin{aligned}
 & \min cx \\
 & A^k x \geq b^k - M^k(1 - \delta_k), \quad k \in K, \\
 & x \in \mathbb{R}^n, \quad x_j \in \mathbb{Z} \quad \text{for } j \in J, \quad \delta_k \in \{0, 1\} \\
 & \text{for } k \in K,
 \end{aligned} \tag{13}$$

where

$$\begin{aligned}
 M^k = b^k - \min_{\ell \neq k} \left\{ \min_x \left\{ A^\ell x \mid A^\ell x \geq b^\ell, x \in \mathbb{R}^n, \right. \right. \\
 \left. \left. x_j \in \mathbb{Z} \quad \text{for } j \in J \right\} \right\}.
 \end{aligned} \tag{14}$$

When auxiliary variable $\delta_k = 1$, the k th linear system $A^k x \geq b^k$ is enforced. When $\delta_k = 0$, the k th system is deactivated by subtracting a vector M^k of large numbers from the right-hand side. The components of M^k are chosen in Equation (14) to be as small as possible, so as to result in a tighter relaxation, but larger values yield a correct model.

The *convex hull MILP formulation* introduces continuous auxiliary variables by disaggregating x into a sum $\sum_{k \in K} x^k$, where each x^k corresponds to the k th disjunct.

Theorem 3. *If an optimization problem $\mathcal{O}$ satisfies the conditions of Theorem 1, it is represented by the formulation*

$$\begin{aligned}
 & \min cx \\
 & x = \sum_{k \in K} x^k A^k x^k \geq b^k \delta_k, \quad k \in K, \\
 & \sum_{k \in K} \delta_k = 1 \quad x \in \mathbb{R}^n, \quad x_j \in \mathbb{Z} \quad \text{for } j \in J, \\
 & \delta_k \in \{0, 1\} \quad \text{for } k \in K.
 \end{aligned} \tag{15}$$

The convex hull formulation (Eq. 15) has the advantage that it provides the tightest possible linear relaxation of $\mathcal{O}$, namely a *convex hull relaxation*. That is, its continuous relaxation describes a set that, when projected onto x , is the closure of the convex hull of $\mathcal{O}$'s feasible set. This assumes that the individual systems $A^k x \geq b^k$ provide convex hull relaxations—as they do, for example, when all the x_j s are continuous.

The model represented by Equation (15) continues to provide a valid convex hull

relaxation of $\mathcal{O}$ when the recession cone condition is not satisfied, even though Equation (15) does not correctly represent $\mathcal{O}$ in this case. In addition, the model (15) is *locally ideal*, meaning that the 0–1 variables δ_k take integer values at every extreme point of the polyhedron described by the model's linear relaxation.

The big- M formulation (Eq. 13) likewise provides a valid relaxation of $\mathcal{O}$ even when the polyhedra do not have the same recession cone, although not in general a convex hull relaxation. The big- M formulation need not be locally ideal.

It is hard to say, in general, when a big- M formulation is preferable to a convex hull formulation. It tends to be more attractive when there are a large number of disjuncts, because the convex hull model introduces a vector x^k of auxiliary continuous variables for every disjunct. In some cases, the big- M model provides a convex hull relaxation. On the other hand, the convex hull model may simplify, and some variables may drop out.

In practice, a problem typically has several disjunctive constraints. (A system of knapsack constraints can be regarded as a disjunction with a single disjunct.) The MILP formulations of the disjunctions are pooled to form an MILP model. Note that while convex hull formulations provide convex hull relaxations of the individual disjunctions, when taken together they do not necessarily provide a convex hull relaxation of the problem as a whole.

Modeling the Fixed-Charge Function

The fixed-charge problem can be modeled by writing a big- M or a convex hull formulation of the disjunctive problem (Eq. 8). In this case, the two formulations turn out to be identical.

The big- M formulation (Eq. 13) of Equation (8) is

$$\begin{aligned}
 0 &\leq x \leq M_1^1 \delta & 0 &\leq x \leq U + M_1^2(1 - \delta), \\
 z &\geq -M_2^1 \delta & z &\geq cx + f - M_2^2(1 - \delta), \\
 \delta &\in \{0, 1\},
 \end{aligned} \tag{16}$$

where δ_1, δ_2 are written as $\delta, 1 - \delta$ because they sum to one. From Equation (14), $(M_1^1, M_2^1, M_1^2, M_2^2) = (U, -f, 0, f)$. So Equation (16) simplifies to Equation (11).

The convex hull formulation (Eq. 15) of Equation (8) is

$$\begin{aligned} x &= x^1 + x^2 & z &= z^1 + z^2, \\ x^1 &= 0 & 0 &\leq x^2 \leq U\delta, \\ z^1 &\geq 0 & z^2 &\geq cx^2 + f\delta, \\ \delta &\in \{0, 1\}. \end{aligned}$$

Because δ_1 does not appear in the model for the first disjunct, δ_2 is written as δ . The fact that $x^1 = 0$ means that x can replace x^1 . Also z^1 can be removed by writing $z \geq z^2$. Because z_2 is minimized, z can now replace z_2 , and the model again simplifies to Equation (11). The feasible set of Equation (11)'s continuous relaxation projects onto the convex hull of the feasible set in x_1, x_2 -space, as illustrated in Fig. 2b.

EXAMPLES OF MILP MODELING

The disjunctive modeling approach may seem a roundabout way to obtain a fairly obvious model for the fixed-charge function. However, it provides a general tool for constructing good formulations that are much less obvious for more complex problems. This is illustrated by the following examples.

Capacitated Facility Location

The transportation problem described earlier assumes that factories already exist at all of the factory sites. The problem can be modified to address a location as well as a routing issue, at which sites should factories be built?

The problem poses two discrete alternatives for each site i . Either a factory is built or it is not. If it is built, the total shipments out of the location must be at most C_i , and a fixed cost f_i is incurred. Otherwise nothing is shipped out of the location. Thus if x_{ij} is again the quantity transported from i to j , the situation at site i is represented by a disjunction of two knapsack systems

$$\left(\begin{aligned} \sum_{j=1}^n x_{ij} &\leq C_i \\ 0 \leq x_{ij} &\leq K_{ij}y_{ij}, \text{ all } j \\ z_i &= f_i \\ y_{ij} &\in \mathbb{Z}, \text{ all } j \end{aligned} \right) \vee \left(\begin{aligned} x_{ij} &= 0, \text{ all } j \\ z_i &= 0 \end{aligned} \right), \quad (17)$$

where variable z_i represents the fixed cost incurred. Again, each customer j must receive adequate supply

$$\sum_{i=1}^m x_{ij} = D_j, \text{ all } j. \quad (18)$$

This can be viewed as a disjunction with one disjunct. The problem is to minimize

$$\sum_{i=1}^m \left(z_i + \sum_{j=1}^n c_{ij}x_{ij} \right) \quad (19)$$

subject to Equation (18), and subject to Equation (17) for all i .

The polyhedra defined by the two disjuncts in Equation (17) have different recession cones. The cone for the first polyhedron is $\{(x_i, y_i) \mid x_i = 0, y_i \geq 0\}$, where $x_i = (x_{i1}, \dots, x_{in})$ and $y_i = (y_{i1}, \dots, y_{in})$, while the cone for the second is $\{(x_i, y_i) \mid x_i = 0\}$. However, if we add the innocuous constraint $y_i \geq 0$ to the second disjunct, the two disjuncts have the same recession cone and can be given a convex hull formulation

$$\begin{aligned} \sum_{j=1}^n x_{ij} &\leq C_i\delta_i, \\ 0 \leq x_{ij} &\leq K_{ij}y_{ij}, \text{ all } j \\ z_i &= f_i\delta_i, \quad \delta_i \in \{0, 1\}, \quad y_{ij} \in \mathbb{Z}, \text{ all } j \end{aligned} \quad (20)$$

The resulting MILP model for the entire problem is

$$\min \sum_{i=1}^m \left(f_i\delta_i + \sum_{j=1}^n c_{ij}y_{ij} \right),$$

$$\begin{aligned}
\sum_{j=1}^n x_{ij} &\leq C_i \delta_i, \quad \text{all } i, \\
0 \leq x_{ij} &\leq K_{ij} y_{ij}, \quad \text{all } i, j, \\
\sum_{i=1}^m x_{ij} &= D_j, \quad \text{all } j, \\
\delta_i &\in \{0, 1\}, \quad y_{ij} \in \mathbb{Z}, \quad \text{all } i, j.
\end{aligned} \tag{21}$$

If the big- M formulation (Eq. 13) of the disjunctions is used, rather than the convex hull formulation, the same MILP model results.

Uncapacitated Facility Location

An uncapacitated location problem shows how a disjunctive approach can lead to a tighter relaxation than one might obtain otherwise. The problem is the same as the previous one, except that there is no limit on the capacity of each facility.

A beginner's mistake is to model this as a special case of the capacitated problem. Although there is no capacity limit, one can observe that each factory i will ship at most $\sum_j D_j$ units and therefore let $C_i = \sum_j D_j$ in the formulation (21) for the capacitated problem. This is a valid formulation of the uncapacitated problem, but there is a much tighter one.

Let us begin again with a choice of alternative. If factory i is installed, it supplies at most D_j to each customer j and incurs cost f_i . If it is not installed, then it supplies nothing

$$\left(\begin{array}{l} 0 \leq x_{ij} \leq D_j, \quad \text{all } j \\ 0 \leq x_{ij} \leq K_{ij} y_{ij}, \quad \text{all } j \\ z_i = f_i \\ y_{ij} \in \mathbb{Z}, \quad \text{all } j \end{array} \right) \vee \left(\begin{array}{l} x_{ij} = 0, \quad \text{all } j \\ z_i = 0 \end{array} \right).$$

The convex hull formulation of this disjunction is

$$\begin{aligned}
x_{ij} &\leq D_j \delta_i, \quad \text{all } j, \\
0 \leq x_{ij} &\leq K_{ij} y_{ij}, \quad \text{all } j, \\
z_i &= f_i \delta_i, \quad \delta_i \in \{0, 1\}, \quad y_{ij} \in \mathbb{Z}, \quad \text{all } j.
\end{aligned} \tag{22}$$

This is a tighter MILP formulation than Equation (20) with $C_i = \sum_j D_j$. To see this, note that setting $\delta_i = 1/2$ can satisfy Equation (20) when $x_{ij} > D_j/2$ for some j ,

provided $x_{ik} < D_k/2$ for some $k \neq j$, whereas this solution cannot satisfy Equation (22).

A rule of thumb for MILP modeling is that a more disaggregated model like Equation (22) is tighter. Yet, Equation (22) results simply from using all available information when formulating each disjunct.

Lot Sizing with Setup Costs

A lot sizing problem with setup costs illustrates how logical relations among linear systems can be captured with logical constraints.

There is a demand D_t for a product in each period t . No more than K_t units of the product can be manufactured in period t , and any excess over demand is stocked to satisfy future demand. If there is no production in the previous period, then a setup cost of f_t is incurred. The unit production cost is p_t , and the unit holding cost per period is h_t . A starting stock level s_0 is given. The objective is to choose production levels in each period so as to minimize total cost over all periods.

Let x_t be the production level in period t and s_t the stock level at the end of the period. In each period t , there are three options to choose from: (i) start producing (with a setup cost), (ii) continue producing (with no setup cost), and (iii) produce nothing. If v_t is the setup cost incurred in period t , these correspond respectively to the three disjuncts

$$\left(\begin{array}{l} v_t \geq f_t \\ 0 \leq x_t \leq K_t \end{array} \right) \vee \left(\begin{array}{l} v_t \geq 0 \\ 0 \leq x_t \leq K_t \end{array} \right) \vee \left(\begin{array}{l} v_t \geq 0 \\ x_t = 0 \end{array} \right). \tag{23}$$

There are logical connections between the choices in consecutive periods. If we schematically represent the disjunction Equation (23) as $A_t \vee B_t \vee C_t$, the logical connections can be written as

$$\begin{aligned}
B_t &\Rightarrow (A_{t-1} \vee B_{t-1}), \\
A_t &\Rightarrow (\neg A_{t-1} \wedge \neg B_{t-1}).
\end{aligned} \tag{24}$$

The inventory balance constraints are

$$\begin{aligned}
s_{t-1} + x_t &= D_t + s_t, \quad s_t \geq 0, \\
t &= 1, \dots, n,
\end{aligned} \tag{25}$$

where s_t is the stock level in period t and s_0 is given. The problem is to minimize

$$\sum_{t=1}^n (p_t x_t + h_t s_t + v_t) \quad (26)$$

subject to Equations (23) and (24) for all $t \geq 1$ and Equation (25).

A convex hull formulation for Equation (23) is

$$\begin{aligned} v_t^1 &\geq f_t \alpha_t, & v_t^2 &\geq 0, & v_t^3 &\geq 0, \\ 0 &\leq x_t^1 \leq K_t \alpha_t, & 0 &\leq x_t^2 \leq K_t \beta_t, & x_t^3 &= 0, \\ v_t &= v_t^1 + v_t^2 + v_t^3, & x_t &= x_t^1 + x_t^2 + x_t^3, \\ \alpha_t + \beta_t + \gamma_t &= 1, & \alpha_t, \beta_t, \gamma_t &\in \{0, 1\}. \end{aligned} \quad (27)$$

Thus, $\alpha_t = 1$ indicates a start-up, $\beta_t = 1$ continued production, and $\gamma_t = 1$ no production in period t . To simplify Equation (27), first eliminate γ_t , so that $\alpha_t + \beta_t \leq 1$. Because $x_t^3 = 0$, one can set $x_t = x_t^1 + x_t^2$, which allows one to replace the two capacity constraints in Equation (27) by $0 \leq x_t \leq K_t(\alpha_t + \beta_t)$. Finally, v_t can replace v_t^1 because v_t is minimized. The convex hull formulation (27) becomes

$$\begin{aligned} v_t &\geq f_t \alpha_t, & 0 &\leq x_t \leq K_t(\alpha_t + \beta_t), & (a) \\ \alpha_t + \beta_t &\leq 1, & & & (b) \end{aligned} \quad (28)$$

where $\alpha_t, \beta_t \in \{0, 1\}$. The logical constraints (Eq. 24) can be formulated as

$$\begin{aligned} \alpha_{t-1} + \beta_{t-1} - \beta_t &\geq 0, & (a) \\ -\alpha_{t-1} - \alpha_t &\geq -1, & -\beta_{t-1} - \alpha_t \geq -1. & (b) \end{aligned} \quad (29)$$

The set packing inequalities in Equation (29b) and $\alpha_{t-1} + \beta_{t-1} \leq 1$ from Equation (28b) can be replaced by the clique inequality

$$\alpha_{t-1} + \beta_{t-1} + \alpha_t \leq 1. \quad (30)$$

The entire problem can now be formulated as minimizing Equation (26) subject to Equation (25) along with Equations (28a), (29a), (30), and $\alpha_t, \beta_t \in \{0, 1\}$ for all $t \geq 1$.

Package Delivery

A final example, adapted from Refs 3 and 4, illustrates how a principled modeling approach incorporates two modeling tricks that one might otherwise miss. A collection of packages are to be delivered by several trucks, and each package j has size a_j . Each available truck i has capacity Q_i and costs c_i to operate. The problem is to decide which trucks to use, and which packages to load on each truck, to deliver all the items at minimum cost.

The decision problem consists of two levels: the choice of which trucks to use, followed by the choice of which packages to load on each truck. The trucks selected must provide sufficient capacity, which leads naturally to a 0–1 knapsack constraint

$$\sum_i Q_i \delta_i \geq \sum_j a_j, \quad (31)$$

where each $\delta_i \in \{0, 1\}$ and $\delta_i = 1$ when truck i is selected.

The secondary choice of which packages to load on truck i depends on whether that truck is selected. If the truck i is selected, then a cost c_i is incurred, and the items loaded must fit into the truck (a 0–1 knapsack constraint). If truck i is not selected, then no items can be loaded. The disjunction is

$$\left(\begin{array}{l} z_i \geq c_i \\ \sum_j a_j x_{ij} \leq Q_i \\ 0 \leq x_{ij} \leq 1, \text{ all } j \\ x_{ij} \in \mathbb{Z}, \text{ all } j \end{array} \right) \vee (x_{ij} = 0, \text{ all } j), \quad (32)$$

where z_i is the fixed cost incurred by truck i , and $x_{ij} = 1$ when package j is loaded into truck i . The associated polyhedra have the same recession cone if one adds $z_i \geq 0$ to the second disjunct. Because $\delta_i = 1$ when truck i is selected, the convex hull formulation of Equation (32) is

$$\begin{aligned} z_i &\geq c_i \delta_i, & (a) \\ \sum_j a_j x_{ij} &\leq Q_i \delta_i, & (b) \\ x_{ij} &\leq \delta_i, \text{ all } j, & (c) \\ \delta_i, x_{ij} &\in \{0, 1\}, \text{ all } j. \end{aligned} \quad (33)$$

Finally, set covering inequalities ensure that each package is shipped

$$\sum_i x_{ij} \geq 1, \quad x_{ij} \in \{0, 1\}, \quad \text{all } j. \quad (34)$$

One can now minimize total fixed cost $\sum_i z_i$ subject to Equations (31) and (34), as well as Equation (33) for all i .

This formulation differs in two ways from a formulation that one might initially write for this problem. One might omit the constraint (33c) because the model is correct without it. Yet this constraint makes the relaxation tighter. Also, one might not include constraint (31), because due to Equation (34), it is the sum of constraints (33b) over all i . Yet the presence of Equation (31) allows the solver to deduce lifted knapsack cuts, which create a tighter continuous relaxation. This results in much faster solution.

PIECEWISE LINEAR FUNCTIONS

Piecewise linear functions are a very useful modeling tool because they can be used to approximate separable nonlinear functions in an MILP model. Typically, one wishes to model a function of the form $g(x) = \sum_j g_j(x_j)$ by approximating each nonlinear term $g_j(x_j)$ with a piecewise linear function $f_j(x_j)$. The function $f_j(x_j)$ is set to a value equal to (or close to) $g_j(x_j)$ at a finite number of values of x_j and is defined between these points by a linear interpolation.

It is convenient to drop the subscripts and refer to $f_j(x_j)$ as $f(x)$. For the sake of generality, suppose that $f(x)$ is piecewise linear in the sense that it is linear on possibly disjoint intervals $[a_i, b_i]$ and undefined outside these intervals, as illustrated in Fig. 3. More precisely, $x \in \bigcup_{i=1}^k [a_i, b_i]$ and

$$f(x) = \begin{cases} f(a_i) + \frac{x - a_i}{b_i - a_i} [f(b_i) - f(a_i)] & \text{if } x \in [a_i, b_i] \text{ and } a_i < b_i, \\ f(a_i) & \text{if } x = a_i = b_i. \end{cases} \quad (35)$$

In many applications, each $b_i = a_{i+1}$, which means $f(x)$ is continuous.

A disjunctive formulation is natural and convenient for a function of this form

$$\bigvee_i \left(\begin{array}{l} x = \lambda a_i + \mu b_i \\ z = \lambda f(a_i) + \mu f(b_i) \\ \lambda + \mu = 1, \quad \lambda, \mu \geq 0 \end{array} \right), \quad (36)$$

where disjunct i corresponds to $x \in [a_i, b_i]$, and z is a variable that represents $f(x)$. Because the disjuncts define polyhedra with the same recession cone (all the polyhedra are bounded), Equation (36) has a locally ideal, convex hull formulation

$$\begin{aligned} x &= \sum_i \lambda_i a_i + \mu_i b_i \\ z &= \sum_i \lambda_i f(a_i) + \mu_i f(b_i) \\ \lambda_i + \mu_i &= \delta_i, \quad \text{all } i \\ \sum_i \delta_i &= 1 \\ \lambda_i, \mu_i &\geq 0, \quad \delta_i \in \{0, 1\}, \quad \text{all } i \end{aligned} \quad (37)$$

This is similar to a well-known textbook model that dispenses with the multipliers μ_i but applies only when $f(x)$ is continuous

$$\begin{aligned} x &= \sum_{i=1}^{k+1} \lambda_i a_i, \quad z = \sum_{i=1}^{k+1} \lambda_i f(a_i), \quad \sum_{i=1}^{k+1} \lambda_i = 1 \quad (a) \\ \lambda_i &\leq \delta_{i-1} + \delta_i, \quad i = 2, \dots, k \quad (b) \\ \lambda_1 &\leq \delta_1, \quad \lambda_{k+1} \leq \delta_k, \quad \sum_{i=1}^k \delta_i = 1 \quad (c) \\ \lambda_i &\geq 0, \quad i = 1, \dots, k+1; \quad \delta_i \in \{0, 1\}, i = 1, \dots, k. \end{aligned} \quad (38)$$

where $a_{k+1} = b_k$. The model is designed to require that at most two λ_i s can be positive, and if two are positive they must be adjacent. However, this model is not as tight as Equation (37) and is not locally ideal [5]. For continuous functions $f(x)$, one can use the *incremental cost model*, which contains no more variables than Equation (38) but is equivalent to the tight model Equation (37) and locally ideal [6]

Figure 3. A piecewise linear function.

$$\begin{aligned}
 x &= a_1 + \sum_{i=2}^{k+1} x_i, \quad z = f(a_1) + \sum_{i=2}^{k+1} \frac{f'_i}{a'_i} x_i \\
 0 &\leq x_i \leq a'_i, \quad i = 2, \dots, k+1 \\
 a'_i \delta_i &\leq x_i \leq a'_i \delta_{i-1}, \quad i = 3, \dots, k \\
 a'_2 \delta_2 &\leq x_2 \leq a'_2, \quad 0 \leq x_{k+1} \leq a'_{k+1} \delta_k \\
 \delta_i &\in \{0, 1\}, \quad i = 2, \dots, k.
 \end{aligned} \tag{39}$$

Here, $a'_i = a_i - a_{i-1}$ and $f'_i = f(a_i) - f(a_{i-1})$.

There are recent proposals for modeling piecewise linear functions with a logarithmic number of 0–1 variables [7–9].

SYMMETRY

Symmetry occurs in an MILP model when values or variables can be exchanged without affecting the problem in any significant way. Symmetries can greatly retard solution of the problem, because the solver may waste time enumerating a large number of equivalent solutions. Symmetries can sometimes be broken by adding constraints to the model, or by reformulating it completely. There are also techniques that deal with symmetries during the solution process.

Value symmetry occurs when the values can be interchanged in a solution without affecting the feasibility or optimality of that solution. For example, any two colors in a graph coloring can be swapped. *Variable symmetry* occurs when variables can be

interchanged in a model without affecting the set of feasible or optimal solutions.

Symmetry-Breaking Constraints

Variable symmetry can often be avoided by adding constraints that prioritize symmetric variables. This is illustrated by the package delivery problem described earlier. Suppose that there are four trucks, with capacities 80, 80, 80, and 100, respectively. There are seven packages, having sizes 30, 30, 30, 40, 40, 50, and 50.

Because trucks 1, 2, and 3 are identical, the variables δ_1, δ_2 , and δ_3 can be interchanged with no effect on the problem. This symmetry can be broken by requiring that truck 1 be used first, followed by truck 2, and then truck 3. This is accomplished with the symmetry-breaking constraint $\delta_1 \geq \delta_2 \geq \delta_3$.

Symmetry-Breaking Reformulation

Because some packages are the same size in the example, they give rise to another variable symmetry. Packages 1, 2, and 3 have the same size, which means that variables x_{i1}, x_{i2} , and x_{i3} can be interchanged for any i , and similarly for the other package sizes. These symmetries can be removed by redefining variables. Let y_{ik} be the number of packages of size k loaded on truck i . Then, the problem is to minimize $\sum_i c_i \delta_i$ subject to Equation (31) and

$$\sum_k \bar{a}_k y_{ik} \leq Q_i \delta_i, \quad \delta_i \in \{0, 1\}, \text{ all } i;$$

$$y_{ik} \geq 0, y_{ij} \in \mathbb{Z}, \text{ all } i, k$$

plus the symmetry-breaking constraints for trucks, where $\bar{a}_k$ is the space consumed by packages of size k .

An alternate approach is to remove both truck and package symmetries by formulating the problem in a manner similar to the crew rostering problem described earlier. A truck of size 80 can be loaded in four ways: 30 + 30, 30 + 40, 30 + 50, and 40 + 40, which can be indexed $\ell = 1, \dots, 4$. A truck of size 100 can be loaded in six ways: 30 + 30 + 30, 30 + 30 + 40, 30 + 50, 40 + 40, 40 + 50, and 50 + 50. Incomplete loadings need not be enumerated. Let $d_{t\ell}$ be a vector whose k th component is the number of packages of size k used in loading pattern ℓ on a truck of type t ($t = 1, 2$). Then the four loading patterns for truck type 1 (capacity 80) are encoded by $d_{11}, \dots, d_{14}$, which are the columns on the left below, while the loading patterns for truck type 2 (capacity 100) appear on the right

2	1	1	0	3	2	1	0	0	0
0	1	0	2	0	1	0	1	2	0
0	0	1	0	0	0	1	1	0	2

The rows correspond to packages of sizes 30, 40, and 50. If variable $z_{t\ell}$ is the number of trucks of type t loaded with pattern ℓ , the MILP model is

$$\min \sum_t \bar{c}_t \sum_\ell z_{t\ell},$$

$$\sum_{t\ell} d_{t\ell} z_{t\ell} \geq b; \quad z_{t\ell} \geq 0, z_{t\ell} \in \mathbb{Z}, \text{ all } t, \ell,$$

where, $\bar{c}_t$ is the capacity of truck type t . The requirements vector b contains the number of packages of each type. In the example, $b = (3, 2, 2)$.

There may be a very large number of loading patterns, but as in the case of crew rostering, the problem can be solved by branch-and-price method.

EXTENSIONS

MILP solvers typically supply features that go beyond MILP modeling and allow more efficient solution. The most common among them include special ordered sets, indicator variables, and semicontinuous variables.

Special Ordered Sets

A *special ordered set of type 1* (SOS1) is a variable set $S = \{x_1, \dots, x_k\}$ for which exactly one variable is allowed to be positive, and the rest must be zero. SOS1 is most commonly used along with a set partitioning constraint $\sum_{j=1}^k x_j = 1$. If the model declares S to be SOS1, there is no need to restrict the variables in the set partitioning constraint to be integer. The solver enforces integrality through a efficient branching scheme that creates a branch for each $x_j \in S$ by fixing all the other variables in S to zero.

Variable set S is a *special ordered set of type 2* (SOS2) when exactly two of the variables are allowed to be positive, the rest must be zero, and any two positive variables must be adjacent (i.e., x_j and x_{j+1} for some j). SOS2 is designed to simplify the model (Eq. 38) of a piecewise linear function. By declaring $\{\lambda_1, \dots, \lambda_{k+1}\}$ to be SOS2, only constraints (a) of Equation (38) need be included in the model. SOS2 is also implemented by an efficient branching scheme, but it sacrifices the convex hull relaxation provided by the tighter MILP models (37) and (39). In addition, it is unsuitable for a discontinuous piecewise linear function like that in Fig. 3. Further options are discussed in Ref. 10.

Indicator Constraints and Semicontinuous Variables

Indicator constraints are constraints that are enforced only when a 0–1 variable is equal to 1. Thus if one wishes to enforce $ax \geq \beta$ only when $\delta = 1$, the pair $(\delta, ax \geq \beta)$ is declared an indicator constraint. This device can obviously be encoded with MILP constraints. The indicator constraint obviates the encoding but sacrifices the continuous relaxation it provides.

A *semicontinuous* variable x is a related idea in which x is forced to zero when $\delta = 0$

and to be within bounds $L \leq x \leq U$, when $\delta = 1$. The MILP encoding is similar to that of a discontinuous piecewise linear function. No encoding is necessary if x is declared a semicontinuous variable.

FURTHER READING

General guidance on MILP modeling can be found in Refs 1, and 11–13. Modeling of logical conditions is further explained in Refs 14 and 15. The traveling salesman problem presents an interesting challenge for MILP modeling, and several formulations are discussed in Ref. 16. A recent trend is to integrate MILP modeling with constraint programming models, because this provides a richer modeling framework that can allow the solver to exploit special structure in the problem [14,17].

BACKGROUND AND INTRODUCTION

Nonlinearly constrained optimization problems (NCOs) are an important class of problems with a broad range of engineering, scientific, and operational applications. For ease of presentation, we consider NCOs of the form

$$\underset{x}{\text{minimize}} \ f(x) \quad \text{subject to} \ c(x) = 0 \text{ and } x \geq 0, \quad (1)$$

where the objective function, $f: \mathbb{R}^n \rightarrow \mathbb{R}$, and the constraint functions, $c: \mathbb{R}^n \rightarrow \mathbb{R}^m$, are twice continuously differentiable. We denote the multipliers corresponding to the equality constraints, $c(x) = 0$, by y and the multipliers of the inequality constraints, $x \geq 0$, by $z \geq 0$. An NCO may also have unbounded variables, upper bounds, or general range constraints of the form $l_i \leq c_i(x) \leq u_i$, which we omit for the sake of simplicity.

In general, one cannot solve Equation (1) directly or explicitly. Instead, an iterative method is used that solves a sequence of simpler, approximate subproblems to generate a sequence of approximate solutions, $\{x_k\}$, starting from an initial guess, x_0 . Every subproblem may in turn be solved by an iterative process. These inner iterations are also referred to as *minor iterations*. A simplified algorithmic framework for solving Equation (1) is as follows:

Algorithm 1. Framework for nonlinear optimization methods

```

Given initial estimate  $(x_0, y_0, z_0) \in \mathbb{R}^{n+m+n}$ ,
set  $k = 0$ ;
while  $x_k$  is not optimal do
    repeat
        Approximately solve and refine an approximate subproblem of Equation (1) around  $x_k$ .
    until improved solution estimate  $x_{k+1}$  found;
    Check whether  $x_{k+1}$  is optimal; set  $k = k + 1$ .
end

```

In this article, we review the basic components of methods for solving NCOs. In particular, we review the four fundamental components of Algorithm 1: the *convergence test* that checks for optimal solutions or detects failure; the *approximate subproblem* that computes an improved new iterate; the *globalization strategy* that ensures convergence from remote starting points, by indicating whether a new solution estimate is better than the current estimate; and the *globalization mechanism* that truncates the step computed by the local model to enforce the globalization strategy, effectively refining the local model.

Algorithms for NCOs are categorized by the choice they implement for each of these fundamental components. In the next section, we review the fundamental building blocks of methods for nonlinearly constrained optimization. Our presentation is implementation-oriented and emphasizes the common components of different classes of methods.

Notation. Throughout this paper, we denote iterates by $x_k, k = 1, 2, \dots$, and we use subscripts to indicate functions evaluated at an iterate, for example, $f_k = f(x_k)$ and $c_k = c(x_k)$. We also denote the gradients by $g_k = \nabla f(x_k)$ and the Jacobian by $A_k = \nabla c(x_k)$. The Hessian of the Lagrangian is denoted by H_k .

CONVERGENCE TEST AND TERMINATION CONDITIONS

We start by describing the convergence test, a common component among all NCO

algorithms. The convergence test also provides the motivation for the approximate subproblems that are described next. The convergence analysis of NCO algorithms typically provides convergence only to Karush-Kuhn-Tucker (KKT) points. A suitable approximate convergence test is thus given by

$$\begin{aligned} \|c_k\| \leq \epsilon \quad \text{and} \quad \|g_k - A_k y_k - z_k\| \leq \epsilon \\ \text{and} \quad \|\min(x_k, z_k)\| \leq \epsilon, \end{aligned} \quad (2)$$

where $\epsilon > 0$ is the tolerance and the min in the last expression corresponding to complementary slackness is taken componentwise.

In practice, it may not be possible to ensure convergence to an approximate KKT point, for example, if the constraints fail to satisfy a constraint qualification [1, Chapter 7]. In that case, we replace the second condition by

$$\|A_k y_k + z_k\| \leq \epsilon,$$

which corresponds to a Fritz–John point.

Infeasible Stationary Points

Unless the NCO is convex or some restrictive assumptions are made, methods cannot guarantee convergence even to a feasible point. Moreover, an NCO may not even have a feasible point, and we are interested in a (local) certificate of infeasibility. In this case, neither the approximate subproblem nor the convergence test is adequate to achieve and detect convergence. A more appropriate convergence test and feasibility subproblem can be based on the following feasibility problem:

$$\underset{x}{\text{minimize}} \quad \|c(x)\| \quad \text{subject to} \quad x \geq 0, \quad (3)$$

which can be formulated as a smooth optimization problem by introducing slack variables. Algorithms for solving Equation (3) are analogous to algorithms for NCOs, because the feasibility problem can be reformulated as a smooth NCO by introducing additional variables. In general, we can replace this objective by any weighted norm. A suitable convergence test is then

$$\|A_k y_k - z_k\| \leq \epsilon \quad \text{and} \quad \|\min(x_k, z_k)\| \leq \epsilon,$$

where y_k are the multipliers or weights corresponding to the norm used in the objective of Equation (3). For example, if we use the ℓ_1 norm, then if $[c_k]_i < 0$, $[y_k]_i = -1$, if $[c_k]_i > 0$, $[y_k]_i = 1$, and $-1 \leq [y_k]_i \leq 1$ otherwise. The multipliers are readily computed as a by-product of solving the subproblem.

APPROXIMATE SUBPROBLEM: IMPROVING A SOLUTION ESTIMATE

One key difference among nonlinear optimization methods is how the approximate subproblem is constructed. The goal of the approximate subproblem is to provide a *computable* step that improves on the current iterate. We distinguish three broad classes of approximate subproblems: sequential linear models, sequential quadratic models, and interior-point models. Methods that are based on the augmented Lagrangian method are more suitably described in the context of globalization strategies in the section titled “Globalization Strategy: Convergence from Remote Starting Points.”

Sequential Linear and Quadratic Programming

Sequential linear and quadratic programming methods construct a linear or quadratic approximation of Equation (1) and solve a sequence of such approximations, converging to a stationary point.

Sequential Quadratic Programming (SQP) Methods. Sequential quadratic programming (SQP) methods successively minimize a quadratic model, $m_k(d)$, subject to a linearization of the constraints about x_k [2–4] to obtain a displacement $d := x - x_k$.

$$\begin{aligned} \underset{d}{\text{Minimize}} \quad m_k(d) &:= g_k^T d + \frac{1}{2} d^T H_k d \\ \text{subject to} \quad c_k + A_k^T d &= 0, \quad x_k + d \geq 0, \end{aligned} \quad (4)$$

where $H_k \simeq \nabla^2 \mathcal{L}(x_k, y_k)$ approximates the Hessian of the Lagrangian and y_k is the multiplier estimate at iteration k . The new iterate is $x_{k+1} = x_k + d$, together with the multipliers y_{k+1} of the linearized constraints of Equation (4). If H_k is not positive-definite on the null-space of the active constraint

normals, then the quadratic programming (QP) is nonconvex, and SQP methods seek a local minimum of Equation (4). The solution of the QP subproblem can become computationally expensive for large-scale problems because the null-space method for solving QPs requires the factorization of a dense reduced-Hessian matrix. This bottleneck has led to the development of other methods that use linear programming (LP) solutions in the approximate subproblem, and these approaches are described next.

Sequential Linear Programming (SLP) Methods. Sequential linear programming (SLP) methods construct a linear approximation to Equation (1). In general, this LP will be unbounded, and SLP methods require the addition of a trust region (discussed in more detail in the next section):

$$\begin{aligned} & \underset{d}{\text{minimize}} \quad m_k(d) = g_k^T d \\ & \text{subject to} \quad c_k + A_k^T d = 0, \quad x_k + d \geq 0, \\ & \text{and} \quad \|d\|_\infty \leq \Delta_k, \end{aligned} \quad (5)$$

where $\Delta_k > 0$ is the trust-region radius. Griffith and Stewart [5] used this method without a trust region but with the assumption that the variables are bounded. In general, $\Delta_k \rightarrow 0$ must converge to zero to ensure convergence. SLP methods can be viewed as steepest descent methods and typically converge only linearly. If, however there are exactly n active and linearly independent constraint normals at the solution, then SLP reduces to Newton's method for solving a square system of nonlinear equations and converges superlinearly.

Sequential Linear/Quadratic Programming (SLQP) Methods. Sequential linear/quadratic programming (SLQP) methods combine the advantages of the SLP method (fast solution of the LP) and SQP methods (fast local convergence) by adding equality-constrained quadratic programming (EQP) to the SLP method [6–8]. SLQP methods thus solve two subproblems: first, an LP is solved to obtain a step for the next iteration and also an estimate of the active set $\mathcal{A}_k := \{i : [x_k]_i + \hat{d}_i = 0\}$ from a solution $\hat{d}$ of Equation (5). This

estimate of the active set is then used to construct an EQP, on the active constraints,

$$\begin{aligned} & \underset{d}{\text{minimize}} \quad q_k(d) = g_k^T d + \frac{1}{2} d^T H_k d \\ & \text{subject to} \quad c_k + A_k^T d = 0, \\ & \quad [x_k]_i + d_i = 0, \quad \forall i \in \mathcal{A}_k. \end{aligned} \quad (6)$$

If H_k is second-order sufficient (i.e., positive-definite on the null-space of the constraints), then the solution of Equation (6) is equivalent to the following linear system obtained by applying the KKT conditions to the EQP:

$$\begin{bmatrix} H_k & -A_k & -I_k \\ A_k^T & 0 & 0 \\ I_k^T & 0 & 0 \end{bmatrix} \begin{pmatrix} x \\ y_A \end{pmatrix} = \begin{pmatrix} -g_k + H_k x_k \\ -c_k \\ 0 \end{pmatrix},$$

where $I_k = [e_i]_{i \in \mathcal{A}_k}$ are the normals of the active inequality constraints. By taking a suitable basis from the LP simplex solve, SLQP methods can ensure that $[A_k : I_k]$ has full rank. Linear solvers such as MA57 can also detect the inertia; and if H_k is not second-order sufficient, a multiple of the identity can be added to H_k to ensure descent of the EQP step.

Sequential Quadratic/Quadratic Programming (SQQP) Methods. Sequential quadratic/quadratic programming (SQQP) methods have recently been proposed as SQP types of methods [9,10]. First, a convex QP model constructed by using a positive-definite Hessian approximation is solved. The solution of this convex QP is followed by a reduced inequality constrained model or an EQP with the exact second derivative of the Lagrangian.

Theory of Sequential Linear/Quadratic Programming Methods. If H_k is the exact Hessian of the Lagrangian and if the Jacobian of the active constraints has full rank, then SQP methods converge quadratically near a minimizer that satisfies a constraint qualification and a second-order sufficient condition [4].

It can also be shown that, under the additional assumption of strict complementarity, all four methods identify the optimal active set in a finite number of iterations.

The methods described in this section are also often referred to as *active-set methods*, because the solution of each LP or QP provides not only a suitable new iterate but also an estimate of the active set at the solution.

Interior-Point Methods

Interior-point methods (IPMs) are an alternative approach to active-set methods. Interior-point methods are a class of perturbed Newton methods that postpone the decision of which constraints are active until the end of the iterative process. The most successful IPMs are primal–dual IPMs, which can be viewed as Newton’s method applied to the perturbed first-order conditions of Equation (1):

$$0 = F_\mu(x, y, z) = \begin{pmatrix} \nabla f(x) - \nabla c(x)^T y - z \\ c(x) \\ Xz - \mu e \end{pmatrix}, \quad (7)$$

where $\mu > 0$ is the barrier parameter, $X = \text{diag}(x)$ is a diagonal matrix with x along its diagonal, and $e = (1, \dots, 1)$ is the vector of all ones. Note that, for $\mu = 0$, these conditions are equivalent to the first-order conditions except for the absence of the nonnegativity constraints $x, z \geq 0$.

IPMs start at an “interior” iterate $x_0, z_0 > 0$ and generate a sequence of interior iterates $x_k, z_k > 0$ by approximately solving the first-order conditions Equation (7) for a decreasing sequence of barrier parameters. IPMs can be shown to be polynomial-time algorithms for convex nonlinear programming (NLP) [11].

Newton’s method applied to the primal–dual system of Equation (7) around x_k gives rise to the approximate subproblem,

$$\begin{bmatrix} H_k & -A_k & -I \\ A_k^T & 0 & 0 \\ Z_k & 0 & X_k \end{bmatrix} \begin{pmatrix} \Delta x \\ \Delta y \\ \Delta z \end{pmatrix} = -F_\mu(x_k, y_k, z_k), \quad (8)$$

where H_k approximates the Hessian of the Lagrangian, $\nabla^2 \mathcal{L}_k$, and the step $(x_{k+1},$

$y_{k+1}, z_{k+1}) = (x_k, y_k, z_k) + (\alpha_x \Delta x, \alpha_y \Delta y, \alpha_z \Delta z)$ is safeguarded to ensure that $x_{k+1}, z_{k+1} > 0$ remain strictly positive. A sketch of IPM is given in Algorithm 2.

Algorithm 2. Primal–dual interior-point method

Given an initial solution estimate (x_0, y_0, z_0) ,
such that $(x_0, z_0) > 0$.
Choose a barrier parameter μ_0 , $0 < \sigma < 1$, and a
sequence $\epsilon_k \searrow 0$.
repeat
 Set $(x_{k,0}, y_{k,0}, z_{k,0}) = (x_k, y_k, z_k)$, $l = 0$.
 repeat
 Approximately solve the Newton system (8)
 for a new iterate $(x_{k,l+1}, y_{k,l+1}, z_{k,l+1})$.
 Set $l = l + 1$.
 until $\|F_{\mu_k}(x_{k,l}, y_{k,l}, z_{k,l})\| \leq \epsilon_k$;
 Reduce the barrier parameter $\mu_{k+1} = \sigma \mu_k$,
 and set $k = k + 1$.
until x_k, y_k, z_k optimal;

Relationship to Barrier Methods. Primal–dual IPMs are related to earlier barrier methods [12]. These methods were given much attention in the 1960s but soon lost favor because of the ill-conditioning of the Hessian. They regained attention in the 1980s after it was shown that these methods can provide polynomial-time algorithms for LP problems. See the surveys [13–15] for further material. Barrier methods approximately solve a sequence of barrier problems,

$$\begin{aligned} & \underset{x}{\text{minimize}} \quad f(x) - \mu \sum_{i=1}^n \log(x_i) \\ & \text{subject to} \quad c(x) = 0, \end{aligned} \quad (9)$$

for a decreasing sequence of barrier parameters $\mu > 0$. The first-order conditions of Equation (9) are given by

$$\nabla f(x) - \mu X^{-1}e - A(x)y = 0 \quad \text{and} \quad c(x) = 0. \quad (10)$$

Applying Newton’s method to this system of equations results in the following linear system:

$$\begin{bmatrix} H_k + \mu X_k^{-2} & -A_k \\ A_k^T & 0 \end{bmatrix} \begin{pmatrix} \Delta x \\ \Delta y \end{pmatrix} = - \begin{pmatrix} g_k - \mu X_k^{-1}e - A_k y_k \\ c_k \end{pmatrix}.$$

Introducing first-order multiplier estimates $Z(x_k) := \mu X_k^{-1}$, which can be written as $Z(x_k)X_k = \mu e$, we obtain the system

$$\begin{bmatrix} H_k + Z(x_k)X_k^{-1} & -A_k \\ A_k & 0 \end{bmatrix} \begin{pmatrix} \Delta x \\ \Delta y \end{pmatrix} = - \begin{pmatrix} g_k - \mu X_k^{-1}e - A_k y_k \\ c_k \end{pmatrix},$$

which is equivalent to the primal–dual Newton system (8), where we have eliminated

$$\Delta z = -X^{-1}Z\Delta x - Ze - \mu X^{-1}e.$$

Thus, the main difference between classical barrier methods and the primal–dual IPMs is that Z_k is not free for barrier methods but is chosen as the primal multiplier $Z(x_k) = \mu X_k^{-1}$. This freedom in the primal–dual method avoids some difficulties with ill-conditioning of the barrier Hessian.

Convergence of Barrier Methods. If there exists a compact set of isolated local minimizers of Equation (1) with at least one point in the closure of the strictly feasible set, then it follows that barrier methods converge to a local minimum [13].

GLOBALIZATION STRATEGY: CONVERGENCE FROM REMOTE STARTING POINTS

The approximate subproblems of the preceding section guarantee convergence only in a small neighborhood of a regular solution. Globalization strategies are concerned with ensuring convergence from remote starting points to stationary points (and should not be confused with global optimization). To ensure convergence from remote starting points, we must monitor the progress of the iterates generated by the approximate subproblem. Monitoring is easily done in unconstrained optimization, where we can measure progress by comparing objective values. In constrained optimization, however, we must take the constraint violation into account. Three broad classes of strategies exist: augmented Lagrangian methods, penalty and

merit-function methods, and filter and funnel methods.

Augmented Lagrangian Methods

The augmented Lagrangian of Equation (1) is given by

$$\mathcal{L}(x, y, \rho) = f(x) - y^T c(x) + \frac{\rho}{2} \|c(x)\|_2^2, \quad (11)$$

where $\rho > 0$ is the penalty parameter. The augmented Lagrangian is used in two modes to develop algorithms for solving Equation (1): by defining a linearly constrained problem or by defining a bound-constrained problem.

Linearly Constrained Lagrangian Methods.

These methods successively minimize a shifted augmented Lagrangian subject to a linearization of the constraints. The shifted augmented Lagrangian is defined as

$$\bar{\mathcal{L}}(x, y, \rho) = f(x) - y^T p_k(x) + \frac{\rho}{2} \|p_k(x)\|_2^2, \quad (12)$$

where $p_k(x)$ are the higher-order nonlinear terms at the current iterate x_k , that is,

$$p_k(x) = c(x) - c_k - A_k^T(x - x_k). \quad (13)$$

This approach results in the following approximate subproblem:

$$\begin{aligned} & \underset{x}{\text{minimize}} \quad \bar{\mathcal{L}}(x, y_k, \rho_k) \\ & \text{subject to} \quad c_k + A_k^T(x - x_k) = 0, \quad x \geq 0. \end{aligned} \quad (14)$$

We note that if $c_k + A_k^T(x - x_k) = 0$, then minimizing the shifted augmented Lagrangian is equivalent to minimizing the Lagrangian over these constraints. Linearly constrained, augmented Lagrangian methods solve a sequence of problems (14) for a fixed penalty parameter. Multipliers are updated by using a first-order multiplier update rule,

$$y_{k+1} = y_k - \rho_k c(x_{k+1}), \quad (15)$$

where x_{k+1} solves Equation (14). We observe, that augmented Lagrangian methods iterate on the dual variables, unlike the active-set, or IPMs of the previous sections.

Bound-Constrained Lagrangian Methods.

These methods approximately minimize the augmented Lagrangian,

$$\underset{x}{\text{minimize}} \mathcal{L}(x, y_k, \rho_k) \quad \text{subject to } tx \geq 0. \quad (16)$$

The advantage of this approach is that efficient methods for bound-constrained optimization can readily be applied, such as the gradient-projection conjugate-gradient approach [16], which can be interpreted as an approximate Newton method on the active inequality constraints.

Global convergence is promoted by defining two forcing sequences, $\omega_k \searrow 0$, controlling the accuracy with which every bound-constrained problem is solved, and $\eta_k \searrow 0$, controlling progress toward feasibility of the nonlinear constraints. A typical bound-constrained Lagrangian method can then be stated as follows:

Algorithm 3. Bound-constrained augmented Lagrangian method

Given an initial solution estimate (x_0, y_0) , and an initial penalty parameter ρ_0 .

repeat

Set $x_{k,0} = x_k$, $\rho_{k,0} = \rho_k$, $l = 0$, $\text{success} = \text{false}$.

repeat

Find an ω_k -optimal solution $x_{k,l+1}$ of
minimize $\mathcal{L}(x, y_k, \rho_{k,l})$ s.t. $x \geq 0$

if $\|c(x_{k,l+1})\| \leq \eta_k$ **then**

Perform a first-order multiplier update:

$y_{k+1} = y_k - \rho_{k,l} c(x_{k,l+1})$.

Set $\rho_{k+1} = \rho_{k,l}$, and $\text{success} = \text{true}$.

else

Increase penalty: $\rho_{k,l+1} = 10\rho_{k,l}$;
set $l = l + 1$.

end

until $\text{success} = \text{true}$;

Set $x_{k+1} = x_{k,l+1}$, and $k = k + 1$.

until x_k, y_k is optimal;

We note that the inner loop in Algorithm 3 updates the penalty parameter until it is sufficiently large to force progress toward feasibility, at which point the multipliers are updated. Each minimization can be started from the previous iterate, $x_{k,l}$.

Theory of Augmented Lagrangian Methods.

Conn *et al.* [17] show that a bound-constrained Lagrangian method converges globally if the sequence $\{x_k\}$ of iterates is bounded and if the Jacobian of the constraints at all limit points of $\{x_k\}$ has column rank no smaller than m . Conn *et al.* [17] also show that if some additional conditions are met, then their algorithm is R-linearly convergent. Bertsekas [18] shows that the method converges Q-linearly if $\{\rho_k\}$ is bounded, and superlinearly otherwise. Linearly constrained augmented Lagrangian methods can be made globally convergent by adding slack variables to handle infeasible subproblems [19].

Penalty and Merit-Function Methods

Penalty and merit functions combine the objective function and a measure of the constraint violation into a single function whose local minimizers correspond to local minimizers of the original problem (1). Convergence from remote starting points can then be ensured by forcing descent of the penalty or merit function, using one of the mechanisms of the next section.

Exact penalty functions are an attractive alternative to augmented Lagrangians and are defined as

$$p_\rho(x) = f(x) + \rho \|c(x)\|,$$

where $\rho > 0$ is the penalty parameter. Most approaches use the ℓ_1 norm to define the penalty function. It can be shown that a local minimizer, x^* , of $p_\rho(x)$ is a local minimizer of problem (1) if $\rho > \|y^*\|_D$, where y^* are the corresponding Lagrange multipliers and $\|\cdot\|_D$ is the dual norm of $\|\cdot\|$ (i.e., the ℓ_∞ -norm in the case of the ℓ_1 exact-penalty function) [20, Chapter 14.3]. Classical approaches using $p_\rho(x)$ have solved a sequence of penalty problems for an increasing sequence of penalty parameters. Modern approaches attempt to steer the penalty parameter by comparing the predicted decrease in the constraint violation to the actual decrease over a step [21].

A number of other merit functions also exist. The oldest, the quadratic penalty function, $f(x) + \rho \|c(x)\|_2^2$, converges only if

the penalty parameter diverges to infinity. Augmented Lagrangian functions and Lagrangian penalty functions such as $f(x) + y^T c(x) + \rho \|c(x)\|$ have also been used to promote global convergence. A key ingredient in any convergence analysis is to connect the approximate subproblem to the merit function that is being used in a way that ensures a descent property of the merit function; see the section titled “Line-Search Methods.”

Filter and Funnel Methods

Filter and funnel methods provide an alternative to penalty methods that does not rely on the use of a penalty parameter. Both methods use step acceptance strategies that are closer to the original problem, by separating the constraints and the objective function.

Filter Methods. Filter methods keep a record of the constraint violation, $h_l := \|c(x_l)\|$, and objective function value, $f_l := f(x_l)$, for some previous iterates, $x_l, l \in \mathcal{F}_k$ [22]. A new point is acceptable if it improves either the objective function or the constraint violation compared to all previous iterates. That is, $\hat{x}$ is acceptable if

$$f(\hat{x}) \leq f_l - \gamma h_l \quad \text{or} \quad h(\hat{x}) \leq \beta h_l, \quad \forall l \in \mathcal{F}_k,$$

where $\gamma > 0, 0 < \beta < 1$, are constants that ensure that iterates cannot accumulate at infeasible limit points. A typical filter is shown in Fig. 1(a), where the straight lines correspond to the region in the (h, f) -plane that is dominated by previous iterations and the dashed lines correspond to the envelope defined by γ, β .

The filter provides convergence only to a feasible limit because any infinite sequence of iterates must converge to a point, where $h(x) = 0$, provided that $f(x)$ is bounded below. To ensure convergence to a local minimum, filter methods use a standard sufficient reduction condition from unconstrained optimization,

$$f(x_k) - f(x_k + d) \geq -\sigma m_k(d), \quad (17)$$

where $\sigma > 0$ is the fraction of predicted decrease and $m_k(d)$ is the model reduction from the approximate subproblem. It makes sense to enforce this condition only if the model predicts a decrease in the objective function. Thus, filter methods use the switching condition $m_k(d) \geq \gamma h_k^2$ to decide when Equation (17) should be enforced. A new iterate that satisfies both conditions is called an *f-type iterate*, and an iterate for which the switching condition fails is called an *h-type iterate* to indicate that it mostly reduces the constraint violation. If a new point is accepted, then it is added to the current iterate to the filter, $\mathcal{F}_k$, if $h_k > 0$ or if it corresponds to h-type iterations (which automatically satisfy $h_k > 0$).

Funnel Methods. The method of Gould and Toint [23] can be viewed as a filter method with just a single filter entry, corresponding to an upper bound on the constraint violation. Thus, the filter contains only a single entry, $(U_k, -\infty)$. The upper bound is reduced during h-type iterations, to force the iterates toward feasibility; it is left unchanged during f-type iterations. Thus, it is possible to converge without reducing U_k to zero (consistent with the observation that SQP methods converge locally). A schematic interpretation of the funnel is given in Fig. 1(b).

Maratos Effect and Loss of Fast Convergence

One can construct simple examples showing that arbitrarily close to an isolated strict local minimizer, the Newton step will be rejected by the exact penalty function [24], resulting in slow convergence. This phenomenon is known as the *Maratos effect*. It can be mitigated by computing a second-order correction step, which is a Newton step that uses the same linear system with an updated right-hand side [20,25]. An alternative method to avoid the Maratos effect is the use of nonmonotone techniques that require descent over only the last M iterates, where $M > 1$ is a constant.

Figure 1. (a) shows a filter where the grey area corresponds to the points that are rejected by the filter; (b) shows a funnel around the feasible set.

GLOBALIZATION MECHANISMS

In this section, we review two mechanisms to reduce the step that is computed by the approximate subproblem: line-search methods and trust-region methods. Both mechanisms can be used in conjunction with any of the approximate subproblems and any of the global convergence strategies, giving rise to a broad family of algorithms. In the article *Software for Nonlinearly Constrained Optimization*, we describe how these components are used in software for NCOs.

Line-Search Methods

Line-search methods enforce convergence with a backtracking line search along the direction s . For IPMs, the search direction, $s = (\Delta_x, \Delta_y, \Delta_z)$, is obtained by solving the primal-dual system (8). For SQP methods, the search direction is the solution of the QP in Equation (4), $s = d$. It is important to ensure that the model produces a descent direction, e.g., $\nabla \Phi(x_k)^T s < 0$ for a merit or penalty function

$\Phi(x)$; otherwise, the line search may not terminate. A popular line search is the Armijo search [25], described in Algorithm 4 for a merit function $\Phi(x)$. The algorithm can be shown to converge to a stationary point, detect unboundedness, or converge to a point where there are no directions of descent.

Algorithm 4. (Armijo) Line-Search Method for Nonlinear Optimization

Given initial estimate $x_0 \in \mathbb{R}^n$, let $0 < \sigma < 1$, and set $k = 0$;

while x_k is not optimal **do**

 Approximately solve an approximate subproblem of Equation (1) around x_k to find a search direction s .

 Make sure that s is a descent direction, e.g. $\nabla \Phi(x_k)^T s < 0$.

 Set $\alpha^0 = 1$ and $l = 0$.

repeat

 Set $\alpha^{l+1} = \alpha^l/2$ and evaluate $\Phi(x_k + \alpha^{l+1}s)$.

 Set $l = l + 1$.

until $\Phi(x_k + \alpha^l s) \leq f_k + \alpha^l \sigma s^T \nabla \Phi_k$;

 set $k = k + 1$.

end

Line-search methods for filters can be defined in a similar way. Instead of checking descent in the merit function, a filter method is used to check acceptance to a filter. Unlike merit functions, filter methods do not have a simple definition of descent; hence, the line search is terminated unsuccessfully once the step size α^l becomes smaller than a constant. In this case, filter methods switch to a restoration step, obtained by solving a local approximation of Equation (3).

Trust-Region Methods

Trust-region methods explicitly restrict the step that is computed by the approximate subproblem, by adding a trust-region constraint of the form $\|d\| \leq \Delta_k$ to the approximate subproblem. Most methods use an ℓ_∞ -norm trust region, which can be represented by bounds on the variables. The trust-region radius, $\Delta_k > 0$, is adjusted at every iteration depending on how well the approximate subproblem agrees with the NCO, Equation (1).

Algorithm 5. Trust-Region Methods for Nonlinear Optimization

Given initial estimate $x_0 \in \mathbb{R}^n$, choose $\Delta_0 \geq \underline{\Delta} > 0$, and set $k = 0$;

repeat

Reset $\Delta_{k,l} := \Delta_k \geq \underline{\Delta} > 0$; set `success` = false, and $l = 0$.

repeat

Solve an approximate subproblem in a *trust-region*, e.g. Equation (4) with $\|d\| \leq \Delta_{k,l}$.

if $x_k + d$ sufficiently better than x_k **then**

Accept the step: $x_{k+1} = x_k + d$; possibly increase $\Delta_{k,l+1}$; set `success` = true.

else

Reject the step and decrease the trust-region $\Delta_{k,l+1} = \Delta_{k,l}/2$.

end

until `success` = true;

Set $k = k + 1$.

until x_k is optimal;

Step acceptance in this algorithm can be based either on filter methods, or on

sufficient decrease in a merit or penalty function, see Algorithm 4. Trust-region methods are related to regularization techniques, which add a multiple of the identity matrix, $\sigma_k I$, to the Hessian, H_k . Locally, the solution of the regularized problem is equivalent to the solution of a trust-region problem with an ℓ_2 trust-region. One disadvantage of trust-region methods is the fact that the subproblem may become inconsistent as $\Delta_{k,l} \rightarrow 0$. This situation can be dealt with in three different ways: (i) a penalty function approach; (ii) a restoration phase in which the algorithm minimizes the constraint violation [26]; or (iii) a composite step approach [27].

FOUNDATIONS OF DECISION THEORY

LOUIS ANTHONY COX, JR.

Mathematical and Statistical
Sciences, University of Colorado,
Denver, Colorado

A FRAMEWORK FOR DECISION ANALYSIS: ACTS, STATES, AND CONSEQUENCES

Modern decision analysis is based on the following fundamental framework. A decision maker (DM) must choose one among many *alternatives* (often referred to as *acts*) from a set of possible alternatives, A . The DM's choice will be followed by a *consequence*, belonging to a set of possible consequences, C . Which consequence is produced may depend not only on the DM's choice of act, but also on what else happens; this is modeled by calling everything that affects the consequence, other than the DM's choice, the *state of nature* (or, more briefly, the *state*), and by describing the decision problem in terms of a *consequence function* that associates a specific consequence in C with each act–state pair, say (a, s) , from $A \times S$, where A is the “choice set” of possible alternatives (or choices, decisions, and acts); and S is the set of possible states. The consequence function represents the causal relation between acts and their consequences, for each state. (If this relation is uncertain, then it can be included in the definitions of states.) Let $c(a, s)$ denote the consequence that results when the DM takes act a and the state is s . Decision analysis addresses the fundamental problem of deciding *which act in A to choose*, given a consequence function, and informed by preferences for consequences in C , and by any available beliefs or information about states in S .

Example [Choosing the lesser of two evils]. Table 1 represents a simple decision problem, with two possible states (state 1 and state 2) in S and two possible acts (act A and

act B) in the choice set A . This “payoff matrix” representation of the decision problem shows consequence, $c(a, s)$, for each act–state pair.

For example, $c(A, 1) = 2$ deaths, and $c(B, 2) = 5$ deaths. The DM must choose between acts A and B, based on the information summarized in this table, preferences for consequences (which we assume to be such that fewer deaths are preferred to more), and any available information or beliefs about the states. Methods for making such a decision are discussed next.

ALTERNATIVE FORMULATIONS AND NORMATIVE MODELS FOR DECISION MAKING

If the state is modeled as a random variable, with known probabilities for each possible state (or with known probability measures or probability densities, if the state space S is continuous instead of discrete), then another common version of the fundamental decision problem is to decide which act in A to choose, given the *probabilities of consequences* for each act. This version can be derived from the previous one using applied probability. It can be applied even if the consequence function is probabilistic, rather than deterministic. For example, if C, A , and S are all discrete (finite or countable) sets, with known probability $\Pr(s)$ for state s , and if the probability of consequence c occurring when act a is taken and the state is s is denoted by $\Pr(c | a, s)$, then the probability of each consequence c , if act a is selected, can be calculated by “marginalizing out” the state variable, via the following formula (expressing the law of total probability):

$$\begin{aligned}\Pr(c | a) &= \Pr(\text{consequence is } c \text{ if act } a \\ &\quad \text{is selected}) \\ &= \sum_s \Pr(c | a, s) \Pr(s).\end{aligned}\quad (1)$$

(If the state space is continuous, or mixed discrete and continuous, then the above sum

Table 1. A Simple Decision Problem, Represented by a Payoff Matrix

	State 1	State 2
Act A	2 people die	4 people die
Act B	3 people die	5 people die

is replaced by a Lebesgue–Stieltjes integral.) If there are too many states for such explicit enumeration and summation to be convenient, then *Monte Carlo sampling* (in which states are randomly sampled, and probabilities of consequences are estimated by recording how frequently they occur, for each choice of act) may provide a viable alternative way to estimate the probabilities of consequences for each act. $\Pr(c \mid a)$ is called a *consequence model*. The field of *risk assessment* provides constructive methods for estimating consequence models from data.

Most decision analysis formulations of decision problems assume that the DM has *preferences* for consequences and *beliefs* or *information* about states and/or about probabilities of consequences if different acts are chosen. Preferences for consequences are represented by an ordinal *value function*, that is, a function that assigns numbers to consequences so that higher numbers are assigned to preferred consequences. Consequences that are indifferent to each other are assigned the same value number. Examples of value functions include measures of net return from financial investments; lives saved (or life-years saved) by public health interventions; and the objective functions used in optimization problems. Beliefs about states are often represented by (perhaps subjective) probabilities calculated after conditioning on all relevant knowledge and information. Decision analysis then seeks to identify a *most-preferred act*, typically by constructing an ordinal value function for probability distributions over consequences (representing the acts), and then optimizing it, that is, finding an act that maximizes it.

This basic framework of acts, states, and consequences, underpins many specific decision models, developed in other articles. Table 2 lists some important examples. See also the articles titled *Average Reward of a Given MDP Policy* and *Total Expected*

Discounted Reward MDPs: Value Iteration Algorithm

in this encyclopedia. Creatively interpreting A , S , and C allows many powerful decision support and optimization methods to be brought to bear to assist “rational” (consequence-driven) decision making. All of these methods use predicted consequences of acts to optimize decisions.

SOME PRINCIPLES FOR SOLVING DECISION PROBLEMS

Principle 1: Dominance and Stochastic Dominance Criteria

The task of selecting a “best” or most-preferred act in A , given a consequence model $c(a, s)$ can sometimes be simplified by using the principle of *strict dominance*: if one act yields better (preferred) consequences than another for *every* state of nature, that is, no matter how uncertainties are resolved, then it should be preferred. The former act is said to *strictly dominate* the latter. Dominated acts can be eliminated from further consideration, thus simplifying the decision problem. For example, in Table 1, act A strictly dominates act B, as it causes fewer deaths in each state of nature; thus, act B can be eliminated. Such simplification via elimination can be applied even if the probabilities of different states are unknown or have not yet been assessed, and even if the value functions for consequences and acts have not yet been quantified. However, strictly dominated (or strictly dominant acts) do not exist, in many decision problems.

Example [A decision with no strictly dominant acts, solved by stochastic dominance]. Table 3 is a slight rearrangement of the example in Table 1. Now, neither act strictly dominates the other. The best choice depends on the probabilities of the two possible states, which we denote by p for the probability of state 1, and by $1 - p$ for the probability of state 2. If the DM is certain that state 1 will occur ($p = 1$), then the best decision is act A (causing 2 deaths instead of 5). If state 2 is certain to occur ($p = 0$), then the preferred act is B (causing 3 deaths instead of 4).

Table 2. Some Normative Decision-Modeling Frameworks

Framework/ Representation	Act	State	Consequence	Optimization Algorithms
<i>Normal form</i> • Consequence model $c(a, s)$ • State probability model $Pr(s)$ • Utility model $u(c)$	a = act (input to the consequence model)	s = state (input to consequence model)	$c(a, s)$ = consequence model (a matrix or bivariate function)	Mathematical programming: $\text{Max}_{a \in A} \sum_c u(c) \Pr(c a)$ s.t. $\Pr(c a) = \sum_s c(a, s) \Pr(s a)$
<i>Utility table</i> (also called a payoff matrix)	Row of matrix (rows represent the possible acts, in A .)	Column of matrix representing states in S	Value (or payoff) of consequence in cell (usually an NM utility or expected utility)	Eliminate dominated rows, then choose act to maximize expected utility (EU)
<i>Decision tree</i> [1]	Choice of an act at each decision node	Outcome at each chance node	Utilities at tips of tree	Use backward dynamic programming to make choices that maximize EU
<i>Influence diagrams and Bayesian networks</i> [2]	Choice of an act at each decision node	Outcome at each chance node	Value at value node	• Gibbs sampling • Bucket elimination • Graph algorithms (e.g., arc reversal)
<i>Markov decision process (MDP); semi-Markov decision process</i>	Choice of act in each state	Transition time and next state	Reward per unit time in states and/or at transitions; transition rates among states	• Value iteration • Policy iteration • Neurodynamic programming • Linear programming

(continued overleaf)

Table 2. (Continued)

Framework/ Representation	Act	State	Consequence	Optimization Algorithms
<i>Partially observable MDP (POMDP)</i>	Decision rule mapping observations to acts	Underlying state of process	Function of uncertain state and choice of acts, and/or transitions	Similar to MDP. (A POMDP is an MDP with probabilities of states for its state.) Grid and sampling algorithms for large problems
<i>Stochastic optimal control and robust control of uncertain systems</i>	Decision rule (maps observed history to choice of controlled input values)	Probability of next state, given history to date (and inputs)	Function of state and/or control trajectory	Stochastic dynamic programming; adaptive optimization, robust control, reinforcement learning algorithms
<i>Portfolio optimization</i>	Allocation of limited resources among risky investments	Yield from each investment	Return (or loss) from selected resource allocation	Large-scale mathematical programming, robust optimization, and stochastic optimization
<i>Simulation model</i>	Controllable inputs	States of model components	Function of component states and input sequence	Simulation-optimization heuristics and algorithms
<i>Unknown model</i>	Sequence of acts		Sequence of rewards	Adaptive learning, on-line, and minimal-regret algorithms

Table 3. A Payoff Matrix without Strict Dominance

	State 1	State 2
Act A	2 people die	4 people die
Act B	5 people die	3 people die
	$\Pr(\text{state 1}) = p$	$\Pr(\text{state 2}) = 1 - p$

If a DM has no objective basis for assessing p very precisely, but only knows (or judges) that state 1 is at least as probable as state 2, then what should he/she do? Strict dominance does not provide an answer. However, a different criterion called (first-order) *stochastic dominance* can be applied to conclude that any DM who prefers fewer deaths to more in this example should choose act A. The rationale is as follows. Suppose first that $p = 0.5$. (This is the case that is most favorable to selecting act B, given the constraint $p \geq 1 - p$, which is equivalent to $p \geq 0.5$.) Then, choosing act A gives equal chances of 2 or 4 people dying, while choosing act B gives equal chances of 3 or 5 people dying. Thus, the cumulative probability distribution function (CDF) for the number of deaths if B is chosen lies strictly to the right of the CDF for the number of deaths if A is chosen. Therefore, choosing A minimizes not only the expected number of deaths, but the probability that the number of deaths will not exceed any specified number. By this criterion, A is clearly superior to B when $p = 0.5$. If $p > 0.5$, then A is even more preferred to B, since increasing p shifts the CDF for B further to the right of the CDF of A. Thus, the criterion of stochastic dominance allows a clear choice between acts A and B, given partial knowledge of state probabilities (that $p \geq 1 - p$) and partial information about preferences for consequences (fewer deaths are preferred to more). Other dominance criteria (e.g., convex stochastic dominance, which eliminates acts that are dominated by a probability mixture of other acts [3]) have likewise been developed to eliminate some acts, given partial information about preferences and beliefs.

Principle 2: Expected Utility (EU) Criterion

After dominated alternatives have been identified and removed, a “best” act can be

selected from the remaining set of undominated alternatives using optimization methods, provided that preferences and beliefs can be modeled with enough consistency and precision so that a well-defined objective function (an ordinal value function for acts) can be constructed. *Expected utility (EU) theory* provides the best-known normative procedure for extending preferences for consequences to preferences (represented by a value function) for acts. It does so by calculating the EU of an act as follows

$$EU(a) = \sum_c \Pr(c | a)u(c). \quad (2)$$

Here, $u(c)$ is a number called the *utility* [or von Neumann–Morgenstern (NM) utility] of consequence c . In principle, $u(c)$ is defined so that the DM is indifferent between receiving consequence c with certainty and receiving the most-preferred consequence in C with probability $u(c)$, and otherwise receiving the least-preferred consequence in C . This is, admittedly, a rather theoretical and conceptual definition of utility. However, it can be proved that making choices that maximize EU is the *unique* procedure that is consistent with certain normative axioms [1] (e.g., the axioms of *reduction*, stating that choices should be based on probabilities for final consequences, not on interim resolutions of uncertainties; *weak ordering*, stating that alternatives can be consistently rank-ordered by preference, although with ties allowed; *independence*, stating that preferences among alternatives are not changed by uncertainty about whether an opportunity to choose among them will arise; and *continuity*, stating that a unique utility, $u(c)$, can be identified, by the above procedure, for any consequence, c .) Any procedure other than maximizing EU violates one or more of these axioms, giving EU theory a unique normative status as the “gold standard” for a theory of rational decision making.

Real people may have trouble assessing such indifference probabilities in hypothetical lotteries with useful coherence and consistency. In practice, therefore, decision analysts use a variety of other methods to quantify utility functions, $u(c)$, as discussed

in the related articles on *single-attribute utility theory* (SAUT) and *multiattribute utility theory* (MAUT). For example, if C is a set of possible monetary consequences, represented as an interval of the real line, then simple conditions (such as that a risk-averse DM be willing to either buy or sell an uncertain prospect for the same amount, interpreted as the “value” of the prospect) imply that the utility function must have a simple analytic form [such as $u(c) = 1 - \exp(-kc)$, where k expresses the DM’s coefficient of relative risk aversion]. Estimation of utility functions may then be simplified to estimating parameters (such as k), usually from forced-choice data in which the DM expresses preferences between pairs of simple prospects. In any case, the EU functional $EU(a)$ provides an ordinal value function for acts, constructed from the consequence model, $\Pr(c | a)$, and the utility function, $u(c)$. The corresponding normative theory of decision making (justified by axioms that imply it) prescribes choosing an act that maximizes $EU(a)$.

Example [EU Decision Making].

Problem: In Table 3, suppose that p is at most 0.2. Does this constraint give a risk-neutral DM (defined as one who optimizes the expected value of the consequence) enough information to select an act that maximizes EU (here assumed to be equivalent to minimizing expected deaths)?

Solution: The expected number of deaths if A is selected is $2p + 4(1 - p) = 4 - 2p$. The expected number of deaths if B is selected is $5p + 3(1 - p) = 3 + 2p$. Hence, the DM should prefer A to B only if $4 - 2p < 3 + 2p$, or, equivalently, if $p > 0.25$. Hence, knowing that p is at most 0.2 does indeed provide enough information to conclude that B is the EU-maximizing decision for a risk-neutral DM.

Principle 3: Satisficing and Heuristic Decision Making

The set of possible acts may be complex (e.g., all decision rules mapping observations to controlled inputs to a complex system) and

large (e.g., the set of all possible allocations of limited resources among competing investment opportunities). If searching for acts that have relatively high value is itself a costly or time consuming process, then heuristics may be used to abbreviate or simplify the search. This can lead to decisions that are suboptimal in principle, in that they do not necessarily truly optimize the DM’s objective function (or value function for acts), and yet that are pragmatic, in that they outperform other choices that can readily be identified and evaluated, and perhaps reduce the sum of search costs and costs from suboptimal decision making. *Satisficing* refers to decision making, in which the DM stops searching for a better alternative as soon as he/she finds one that is good enough (according to one or more criteria). *Fast, frugal heuristics* are simple decision rules (such as “Do what most others do,” or “Choose the first alternative that is clearly better than others on at least one attribute, and not obviously significantly worse than others on any attribute”) that often work well in familiar task environments, yet require relatively little deliberative thought or analysis [4]. In decision analysis, which seeks to clarify principles and techniques for improving and optimizing decisions, such pragmatic heuristics can usually be criticized, correctly, as leading to needlessly poor (dominated) choices, compared to those that would be produced by more thorough and rigorous analyses. Moving away from the prescriptions of EU theory typically exacts real losses in terms of obtaining less preferred outcomes more often. However, work on decision heuristics does draw attention to the importance, even for normative theories, of considering the costs (including cognitive burden) of decision making itself, and of balancing these against the consequences of suboptimal decisions.

EXTENSIONS OF THE BASIC ACT-STATE CONSEQUENCE FRAMEWORK

The fundamental decision problem, of choosing an act a from A to maximize some value function $V(a)$ [such as EU, if $V(a) = EU(a)$] can be generalized in the following ways.

- *Probabilities of states may depend on the DMs choice of act.* For example, a large company's decision to invest in a certain technology might change the probabilities that others make similar investments, which could affect the probabilities of different consequences for the first investor. If probabilities of states depend on the decision, a , then the probability of consequence c , given act a , is $\Pr(c | a) = \sum_s \Pr(c | a, s) \Pr(s | a)$. EU calculations and stochastic dominance comparisons can then be made using these consequence probabilities.
- *Preferences for consequences may depend on which state occurs.* In this case, the utility function $u(c)$ can be generalized to a state-dependent utility function, $u(c, s)$ [5,6]. State-dependent utilities can be used to model uncertain future preferences, or preferences for a defined set of consequences (such as returns from a financial investment portfolio) that depend on other random events or conditions, not included in the consequence set (such as the life or health of the recipient when the consequence is received).
- *Preferences for consequences may change, depending on previous acts and consequences.* Examples include acquired tastes, adaptation, habit formation, and addiction. Such changes in preferences over time can be modeled in various ways, including via state-dependent utility functions, or explicit dynamic utility functions.
- *Unknown and ambiguous probabilities.* As illustrated in the preceding examples, it may sometimes be necessary or convenient to make decisions with probabilities that are not precisely known, and for which there is no adequate factual basis for selecting a unique prior. [If a unique prior can be specified, then Bayesian inference can be used to condition it on data, producing an updated posterior distribution. Advances in computational methods, such as Markov chain Monte Carlo (MCMC) algorithms and importance

sampling, have made Bayesian inference computationally practical in a wide range of cases, even if convenient conjugate priors are not available, provided that a prior can be specified.] *Robust optimization* of decisions does not require a unique prior, but allows the state probabilities (or probability measures) to belong to a set of possibilities, called an *uncertainty set*. See also the article titled **Introduction to Robust Optimization** in this encyclopedia. Uncertainty sets are usually convex, and may be generated from constraints (such as upper and lower bounds on probabilities of particular states, or of particular events, corresponding to subsets of states.) Normative decision analysis has been extended to allow such sets of probabilities. The *multiple priors model* [7], originally used to model ambiguity-aversion in decision analysis with uncertain probabilities, but subsequently applied to robust control problems [8], provides normative axioms that imply that a DM should select an act from A to maximize the minimum possible value of EU, where the minimum possible value is found by minimizing EU over all probability measures in the uncertainty set.

- *Some acts may have intrinsic value, apart from their consequences.* Intervening to help a person in need, fulfill a duty, prevent an injustice, or right a wrong may carry satisfaction, and strongly affect preferences among acts, no matter what consequences follow. Less benignly, the act of gambling may carry a thrill, quite apart from its probable consequences. In such cases, the distinction between act and consequence is less clear than the idealized normative models suggest, and the separation implicit in the $c(a, s)$, $u(c, s)$, and $\Pr(c | a, s)$ notations may be more artificial than useful. The limited precision and detail used in describing acts and consequences for purposes of decision analysis may also obscure information that is crucial for making decisions. For example, in Table 1, it

seems obvious that act A is preferable to act B, since, no matter which state occurs, act A always results in 1 fewer people dying than would act B. But suppose that we add more detail to this description, by revealing that act B is “do nothing” and act A is “kill Mr. Jones and harvest his blood and organs, then use them to protect the others.” If act A is to sacrifice an innocent, unwilling, and healthy Mr. Jones for the benefit of others, then act A, far from being the obvious dominant choice that it seemed, may now be understood to be an unacceptable violation of Mr. Jones’s rights, with act B being vastly preferable.

- *Unknown consequence functions, and decision making without beliefs.* In new and unfamiliar environments, a rational agent may not at first have any beliefs—or at least no defensible and useful ones—about the probable consequences of alternative acts. Nothing in the A, S, C formalism dictates what should go into these sets. Then, empirical experimentation and learning (from one’s own actions and observed results, or from those of other agents, or both), rather than model-based prediction and optimization, may be crucial to an agent’s survival and well-being. In *evolutionary* and *learning* models of decision making, beliefs and preferences are not needed. Instead, the DM’s behavior is represented by a *decision rule*, mapping observations to probabilities of selecting acts. A DM may then use *reinforcement learning* (see also **Reinforcement Learning Algorithms for MDPs**), in which acts are made more probable when they are associated with larger average experienced rewards; and a population of DMs may undergo *evolution*, to develop decision rules that have high average reward and/or survival probabilities, compared to other possible decision rules. Learning and evolution enable emergence of highly effective (e.g., asymptotically optimal or near-optimal, using criteria such as zero average

regret) decision rules in many environments, even without models of beliefs about states [9,10]. However, the trial and error needed for learning and evolution may be slow, expensive, or potentially fatal. Although the modeling and calculations used in decision analysis typically require more information collection, cognition, and calculation than simple adaptive learning and evolution rules, they can reduce the costs and time to arrive at effective decision rules, at least if the costs of developing usefully accurate consequence models, $c(a, s)$ or $\Pr(c \mid a, s)$, are relatively small compared to the costs of learning or evolving decision rules. Moreover, in many important decision contexts (e.g., one-time major investment decisions), learning and evolution are not practical options, satisficing approaches are too costly, and decision analysis may be the only viable approach.

- *Uncertain acts, consequences, and future preferences.* Some important policy decisions, such as those with very diffuse and/or long-delayed consequences (e.g., regulation of environmental emissions, disposal of high-level radioactive wastes, or interventions to modify possible future climate) have consequences that current decision makers may never observe or know with any confidence, and yet that matter greatly. Moreover, how present decisions affect eventual consequences may depend in part on future acts and adaptations that are difficult or impossible to foresee—for example, because changes in tastes, technology, or understanding will reveal new options, currently unanticipated consequences, or new preferences that are not currently envisioned. Even, the opportunity set A_t of acts available t years in the future may depend on the (currently uncertain) state of the world. A growing literature in economics, management science, and marketing science attempts to extend the foundations and boundaries of decision analysis to include decisions with uncertain future opportunity sets,

consequences, and preferences using concepts such as the economic value of flexibility and reversibility of current decisions when future information becomes available [11–13].

CONCLUSIONS

The basic framework of acts, states, and consequences discussed in this article has provided a very useful foundation for many ingenious practical decision analysis models and algorithms (Table 2) that are now widely used in areas as diverse as economics, manufacturing and logistics, marketing, R&D and risky investments, control engineering, and environmental and public health risk management policy analysis. When the sets A , S , and C are clearly defined, well understood, and capture everything of interest to the decision maker, then decision analysis methods based on these foundations can help to overcome the many limitations and psychological traps of holistic intuitive judgment and decision making, and help practitioners identify better (e.g., dominant or stochastically dominant) decisions [14]. However, our limited ability to know and describe all relevant details of acts, states, and consequences, as well as of beliefs and preferences, in practice—especially future ones—provides a strong incentive to continue refining and extending the normative foundations of decision analysis. Practitioners currently emphasize the need to iteratively refine and check decision models to make sure that they truly capture all (and only) aspects of the situation that should significantly affect a decision, for example, as revealed by sensitivity analysis of simple approximate models [15]. Representing alternative acts by controlled stochastic processes that produce consequences (and perhaps future opportunities, preferences, and decisions) over time, rather than only by probability distributions for final consequences, appears to be a promising direction for generalizing and extending the foundations of decision analysis [13]. Some of the most exciting current directions of research for making decision

analysis better applicable to hard practical problems have been described in this article. After over half-a-century of axiomatic development and in-depth philosophical and mathematical discussion, the foundations of modern decision analysis remain an area of vibrant research. Although the act–state–consequence formalism has proved its value in an enormous range of business, engineering, and policy applications, it seems likely that the most useful and general normative decision theories are yet to come. These will probably build on the foundational work now being done on decision making without clearly known and understood acts, states, consequences, preferences, and beliefs.

Engineering, Rensselaer Polytechnic
Institute, Troy, New York

Simulation modeling is an important step of a simulation study. It concerns with the creation of an efficient simulation model as accurate as needed to mimic the behavior of the underlying system and to reproduce useful observations for subsequent analysis. This introductory article discusses three main simulation modeling methods: discrete-event simulation, continuous simulation, and agent-based simulation. In particular, three discrete-event simulation modeling paradigms are introduced: event scheduling, process interaction, and activity scanning. Several modeling issues are exemplified by a simple single-server queueing system and a slightly more complex multiple-server finite capacity queueing system with impatient customers. Continuous simulation is briefly discussed to draw the differences between discrete-event and continuous simulations. Simulating emergent behavior as a common purpose of agent-based simulation is demonstrated by a classic game of life model and a variation model. Monte-Carlo simulation and other simulation modeling formalisms are briefly highlighted.

INTRODUCTION

Basically, a simulation study involves three steps: modeling, analysis, and presentation. These three steps can be repeated until satisfaction. Modeling is about the creation of an efficient simulation model. Analysis here in a broad sense includes studies of inputs to and outputs from the simulation model, design of experiments, and optimization. The importance of the presentation step is sometimes

underestimated. Presentation is about how to effectively collect and present simulation results and how to communicate with relevant people to improve, verify, and validate (or accredit) the model and results. None of the three steps should be omitted in a professional simulation study.

This introductory article focuses on the first step—modeling. In particular, it deals with computer-based simulation modeling. A computer-based simulation model has the advantages of being low cost, fast, and repeatable. Beginners sometimes find modeling a time consuming task. This is perhaps due to unfamiliarity with either the modeling approach or the software package (or both). This article addresses the former by introducing different simulation modeling approaches. References for using software packages are provided in subsequent discussion. One mistake that beginners often make is the inclination of including as many details as possible into their simulation models. It should be noted that a simulation model is created to satisfy the need of a simulation study, rather than to duplicate the real system exactly. Therefore, the objective of the study matters in simulation modeling.

The modeling power of a simulation modeling approach and the functionalities of the underlying simulation package should also be evaluated separately. It is possible that a less convenient modeling approach implemented by a powerful software platform receives more attention than a more flexible and scalable modeling approach that was executed in a lower-level, less user-friendly programming language. This article does not review the usage, user interface, and functionalities of simulation packages.

Depending on the state of a system and the need of a simulation study, the corresponding simulation model can be discrete, continuous, or hybrid. Strictly speaking, a simulation model is discrete (continuous) if *all* its state variables are discrete (continuous). A model with both discrete and continuous state variables is a hybrid simulation model. There are

also several other ways of classifying simulation models including, static versus dynamic, deterministic versus stochastic, analytic versus numeric, and physical versus computer-based. For example, a simulation model is dynamic if time (simulation clock) is present and static otherwise. Monte-Carlo simulation is one type of static simulation models. Discrete-event and continuous simulations are usually dynamic simulation models [1].

Besides discrete, continuous, and Monte-Carlo simulations, a relatively new simulation paradigm—agent-based simulation—has received increasing attention in various fields over the past two decades. Basically, agent-based simulation, being a bottom-up approach, is capable of modeling systems with intelligent, heterogeneous, and autonomous entities. An agent-based simulation model can be discrete, continuous, or both depending on the type of its state variables. One of the main purposes of agent-based simulation is to simulate known or unknown macroscopic behavior emerging from microscopic interactions.

The rest of the article is organized as follows. The section titled “Discrete-Event Simulation Models” discusses three discrete-event simulation modeling approaches. The section titled “Continuous Simulation Models” outlines continuous simulation models. The section titled “Agent-Based Models” highlights several key concepts in agent-based simulation. The section titled “Monte-Carlo Models” briefly introduces Monte-Carlo simulation. The final section offers a conclusion.

DISCRETE-EVENT SIMULATION MODELS

One special property of a *discrete-event system* is that its state changes only at discrete instants of time. These instants of time represent the occurrences of certain events that change the state of the system and are referred to *event occurrence times* (or simply, *event times*). The system state remains constant in between event times because during which no events occur. This special property facilitates the modeling and analysis of discrete-event simulation because it

allows modelers to focus on the events, their relationships, and durations. To put it in a simple way, creating a discrete-event simulation model is to identify these elements and put them together in a correct manner. This will be demonstrated by examples in the following.

Several concepts in discrete-event simulation modeling are of importance: randomness, dynamics (time evolutions), future-event list (or pending events list or event calendar), and resident and transient entities.

Randomness is the uncertainty in the occurrences of events and durations. Time evolutions are the footprints of the system state with respect to time (both occurred events and their times). Randomness and time evolutions together differentiate a discrete-event simulation model from a standard computer program that is deterministic and static (i.e., no time involved). Almost all simulation packages provide simple mechanisms to implement randomness (i.e., by specifying distributions for event durations and relationships) and handle time evolutions (i.e., by providing access to the current and future simulated times).

A future-event list keeps track of the events scheduled to occur in the simulated future. This list is updated whenever a new event is scheduled to occur in the simulated future. This list is automatically generated and updated in most simulation packages. Users sometimes can also access and modify this list.

Resident entities are objects that reside in the model for a long period of time compared to the simulation run length, for example, a facility, a server, or a queue. Transient entities on the other hand appear in the model for a short period of time, for example, a job, a customer, or a message. The population of resident entities is usually much smaller than that of transient entities. In a typical queueing model, the number of servers is usually less than a hundred while the number of jobs/customers can be tens of thousands or millions. The large population of transient entities poses a computational burden if each of them is stored in memory and requires a certain amount of computation. A more

efficient modeling approach is to keep track of the aggregated information of the transient entities, such as the total number of jobs in queue or the total waiting time of jobs in the system, rather than the individual information, such as the individual waiting time of each job. Because this aggregated information is usually associated with some resident entities, e.g., the queue size, this approach is called the resident-entity approach. The drawback of this approach is that the individual characteristics of the transient entities are lost. Nevertheless, this approach has been shown to significantly improve simulation speed and memory usage [2, 3]. Indeed, it is sometimes possible to avoid memorizing individual characteristics and still be able to obtain the same accuracy

in the simulation results. This is demonstrated in the following example.

A discrete-event simulation model can be created using different world views, which were first discussed in Kiviat [4] and Lackner [5]. Three popular world views: event scheduling, process interaction, and activity scanning, are introduced in the following. Before that, let us first outline a typical algorithm for executing a discrete-event simulation model. This algorithm is essentially an event-scheduling algorithm. Most software packages employ a similar execution algorithm. If one prefers not to use existing simulation packages, he/she can also implement the algorithm by using a general-purpose programming language, such as C/C++.

Discrete-Event Simulation Execution Algorithm

Initialize

Do until stop condition is satisfied

 Advance clock to the time of next event

 Execute event

 Perform actions: change state variables, schedule events, collect statistics, etc.

Event Scheduling

We will use a single-stage multiple-server queueing system with finite capacity and impatient customers (i.e., $G/G/c/K$) to illustrate several basic modeling issues of discrete-event simulation. In this system, there is only one type of transient entities (called *customers*) and they arrive at the system in accordance with an arbitrary stochastic process. Each arriving customer is admitted if the current queue size is less than its capacity (denoted by K). Upon joining the queue, each customer starts a random impatient time period; if he/she does not receive service by the end of the impatient time, he/she will depart the system without being served. The c servers are identical with no vacation and breakdown. This simple model can represent many real-world systems, for example, a bank waiting line with multiple clerks, or a computer communication system (or a call center) in which the entities are the messages or requests stored in buffer and the

servers are the parallel CPUs (or operators) handling these messages/requests.

A good starting point of building a discrete-event simulation model is to have a textual description of a simplified model and try to identify and combine the key events, event relationships, and conditions into a desired logic. After the simplified model is finished, other features can be added to augment the simplified model to create the final model. We will employ this practice to first develop a single-server queueing system with infinite capacity and no impatient customers, and then modify this simplified model to model the original system. A textual description of the single-server queueing simulation is given in the following.

“A simulation **begins** by having the first job **enter** the system. New jobs **enter** the system at random intervals of arrivals. When a job **enters**, *if the resource is available* the job can **start** service. Once a job **starts**, it will **leave** after a service time delay. Whenever

a job **leaves**, *if there is more work waiting*, then service can **start** on the next job” [6].

Almost all information necessary to build this single-server model is embedded in above paragraph. To see this, we highlight the key words in three different formats: bold face, underline, and italics. The words in bold face represent the events: “enter,” “start,” “leave,” and the initial event “begin,” which only executes once. The underlined words denote the random time durations. Here, “random intervals of arrivals” are the interarrival times of the arriving entities, and “service time delay” is the service time duration of each service. The italicized words signify event-scheduling conditions. To build the actual model, circle the events and add arcs starting from the corresponding preceding event and ending at the corresponding succeeding event in each sentence (see Fig. 1). These arcs represent the event relationships. The delay time on each arc is specified by the underlined words if present, or zero otherwise. The condition on each arc is given by the italicized words on that sentence if present, or unconditional otherwise. The resulting simulation model (the right panel of Fig. 1) is an event-scheduling-based simulation model, which is represented by a simulation modeling language called *event relationship graphs*, or simply *event graphs* [7]. Two state variables (Q and R) and two random variables (a and s) are needed: Q returns or sets the current number of customers in the queue, R returns or sets the current number of available servers, a

returns an interarrival time generated from a given distribution (i.e., $a = F_a^{-1}(u)$, where u is a uniform random number between 0 and 1), s returns a service time duration generated from a given distribution (i.e., $s = F_s^{-1}(u)$).

We now ready to extend this model to our final multiple-server system with queue capacity and impatient customers. Two important discrete-event simulation modeling techniques are used: Boolean expressions and look-ahead capability. To model the queue capacity, we note that when a customer arrives, the queue size will increase by one if the current queue size is less than K (i.e., the customer is admitted), and remains unchanged otherwise (i.e., the customer is rejected). This logic can be implemented by using the following Boolean expression:

$$Q = Q + (Q < K), \quad (1)$$

where $(Q < K) = 1$ if the condition is true and zero otherwise.

To model impatient customers without storing the waiting times of all customers (i.e., without resorting to the transient entity approach), we use the look-ahead capability to obtain information in the simulated future. For ease of exposition, we will use a two-server queueing system (i.e., $c = 2$) to illustrate the idea (it can be extended to more than two servers). The idea is as follows. When a customer arrives (say customer i), if he knows the maximum duration he needs

Figure 1. From textual description to simulation model.

In particular, let D be the decision variable of whether to stay or not (stay if $D == 1$ and leave if $D == 0$). Let T_c be current simulation time, which can be obtained by using some system function in most simulation packages (e.g., CLK in Sigma [6] and TNOW in Arena [8]). Let p be the impatient time period of a customer generated from a given distribution, that is, $p \sim F_p(p)$. The state changes that take place when an Enter event occurs are as follows:

The first equation says that a customer will stay (i.e., $D == 1$) if the queue size is less than K (i.e., $(Q < K) == 1$) and the time

The state changes under the Stay event are

The first equation simply generates and stores the service time duration of a customer in s . The second equation computes the actual waiting time of the customer. It is equal to 0 if the arriving customer finds an available server (i.e., $T_1 - T_c < 0$). Otherwise, it is equal to the amount of time before one of the servers is available (i.e., $T_1 - T_c$). The notation “ $(.)^+$ ” represents the positive part of the waiting time (i.e., $\max\{T_1 - T_c, 0\}$). The third and the last equations update the two earliest available times of the servers due to this new arriving customer.

One remark observed from this model is regarding the trade-off between speed and memory. Sometimes, a small amount of auxiliary memory (variables) can greatly reduce

the speed or complexity of the simulation model, such as this one.

Process Interaction

Another popular simulation modeling paradigm is the process-interaction approach. Loosely speaking, for simple systems the process interaction approach is WYSIWYG (*What You See Is What You Get*) in the sense that what you create in the model is what you observe in the real simple system (see Fig. 3 and explanation in next paragraph). (However, this intuitive view diminishes when the complexity of the system increases). This intuitive view is attractive to beginners because it deals directly with the actual objects of a real system. Together with their animation capability, process-interaction-based simulation packages are by far the most common in industry.

To illustrate the intuitive view of process-interaction models, we model the single-server queueing system by using three process-interaction modules to mimic the three processes of the real system: (i) the process of customer arrivals, (ii) the process of queueing customers for service, and (iii) the process of customer departures. We then connect the three modules sequentially so that the entities (customers) can flow through the three modules as they do in the real system. Figure 3 shows the implementation of this model using the simulation package Arena 11 [8]. The mapping between the three modules and the three real processes are also shown in the figure.

To create the model in Arena, just drag the modules from a built-in template of Arena, paste them into the model workspace, connect them based on the job flow, and specify

the data for each module (such as interarrival time and service time distributions, and defining the server) by double clicking the modules. See Kelton *et al.* [8] for details of using Arena.

Two issues of the process-interaction approach should be mentioned: deadlock and virtual entities. Deadlock could occur when two entities are trying to seize the same resources in a wrong sequence. For example, consider two entities (A1 and A2) and two machines (M1 and M2). Let us suppose that A1 is holding M1 and is trying to seize M2 to start a process. At the same time, E2 is holding M2 and needs M1 to start another process. In this situation, unless some mechanism is introduced to break the conflict, both entities and machines will be waiting forever. Therefore, acquisition of resources should be carefully planned when building a process-interaction model. One good rule in practice is to seize *all* required resources at *one* time. In the case where several resources must be seized sequentially (e.g., Process 1 requires only Machine 1 and then immediately Process 2 requires both Machines 1 and 2), then release the previously seized resources first and then seize all needed resources at one time (e.g., release Machine 1 first and then seize both Machines 1 and 2).

Virtual entities are needed when one needs to model some abstract mechanisms or logics that have no physical counterparts in the real system. This is because almost everything in a process-interaction model (including activities, logics, controls, and assigning values to variables) must be driven by flowing entities. For instance, to simulate a traffic intersection, the right-of-way can be modeled as a “virtual resource” and

Figure 3. Process-interaction single-server queueing model and its real-world counterpart.

Figure 4. Process-interaction model of a capacitated queue with multiple servers and impatient customers.

traffics from any directions will need to seize this virtual resource in order to pass the intersection.

Another example of “virtual entities” appears in the multiple-server queueing system with impatient customers. In a process-interaction model, an entity in queue is a passive object in the sense that it cannot proactively trigger activities by itself when certain condition is met. Some mechanism must be created to trigger the corresponding activity. For example, to trigger the departure of an impatient customer whose impatient time has expired, a virtual entity is needed. We use the Arena model shown in Fig. 4 to explain this issue.

An arriving customer, if accepted by the diamond “Not Full?” module based on the current queue size, is assigned an ID in the “Assign ID” module. This customer is then duplicated before joining the queue (the “Start” module). This duplicate is a virtual entity and will stay in the “Impatient Duration” module for a random impatient duration. When the impatient period expires, this virtual entity first identifies itself in the “Retrieve ID” module (because there could be other virtual entities representing other customers). It then enters the “Search Customer from Queue” module to see if the customer that it represents is still waiting in the queue. If not found, the customer either is being served or has left, and this

virtual entity can be disposed. If found, the virtual entity will enter the “Remove Impatient Customer from Queue” module and trigger the departure of the customer from the queue. Both the virtual entity and impatient customer (if found) are then disposed.

From a computational point of view, the process of searching a customer from a queue could be inefficient when the queue size is large. Moreover, the search is done for every customer regardless of whether the customer has left or not. A more efficient approach such as Fig. 2 is therefore recommended for large-scale congested systems.

Other situations where virtual entities are needed include the modeling of resource preventive maintenance and failures, or random events that could change the state of the system. Indeed, virtual entities, when appropriately and professionally handled, can be a powerful modeling technique.

Activity Scanning

An activity-scanning simulation model works by scanning activities of the model and *fires* (i.e., activates) the ones that meet certain given conditions. One of the main benefits of the activity-scanning approach is its analytical property, which facilitates the construction of mathematical models and theoretical analysis. The main representative approach of activity scanning is Petri-net

models [9]. A Petri net is a bipartite graph (i.e., a graph with two types of elements and no two elements of the same type connect to each other). The two types of elements are circles (called *places*) and bars (called *transitions*). Besides these two types of elements, users can also add tokens to the graph to make the Petri net run. Tokens, which are solid dots, are used to represent objects (e.g., jobs or machines) and model logics (e.g., failure events). Each transition represents a certain activity of the model. All the input places to a transition denote the conditions required for the transition to fire. All the output places from a transition are the results of the firing of the transition. In a standard Petri net, a transition is enabled when there is at least one token in each input place. After a time delay associated with the transition (which can be random, deterministic, or zero), the transition fires and one token is removed from each input place. Immediately, one token is added to each output place. The number of tokens entering and leaving from a transition may or may not equal. If the number of tokens in any place is always below a certain number at any time, the Petri net is called *bounded*, otherwise, *unbounded*. At any time of the simulation, a snapshot of the token distribution (their locations) gives the current state of the simulation. This token distribution is called a *marking*.

The aforementioned firing rule is called *remove-on-fire*, in that the tokens are removed when the transition fires. Another firing rule is *remove-on-enable*, which removes the tokens when the transition is enabled. It can be shown that these two rules are equivalent.

To build a Petri-net simulation model, the following four-step procedure can be used:

1. Identify all activities, including zero time activities (one transition for each activity) of the system,
2. Identify the conditions for each activity (one place for each condition),
3. Connect the places and transitions to make the net alive according to the model logic, and
4. Add tokens to represent the initial state of the system.

Fig. 5 presents the four-step implementation of the Petri-net simulation model of the single-server queueing system without capacity and no impatient customers. There are two activities in this simple system: arrivals of customers and services for customers, which are modeled by the two transitions, E and S (which respectively stand for “Enter” and “Start”). The single token in Place A denotes the arrival stream of customers (i.e., the process of arrivals). Every a random time units, Transition E fires; it then places one token to Place Q, denoting an arrival of a customer to the queue, and also puts one token back to Place A, initiating the arrival of the next customer. The token in Place R represents the single machine which is available right now (adding more tokens here extends the model to a multiple-server system). Transition S has two input places, signifying the two conditions for a service to start (i.e., an available server and a waiting customer). When these two conditions are satisfied, Transition S is enabled; and after s random time units, it fires, denoting the completion of a service. One token is then placed in Place R, which allows the server to work on the next customer if there is any. One token is also deposited to Place L, which represents a processed customer.

Figure 5. Activity scanning model of a single-server queueing system.

Enrichments of Petri nets include using colored tokens to represent different types of entities, allowing multiple tokens to be removed from or deposited into a place, and using inhibitor arcs to resolve conflictions by assigning priorities to different activities. The inclusion of inhibitor arcs increases the modeling power of Petri nets to a Turing machine.

Other Discrete-Event Modeling World Views

A discrete-event system can also be characterized by a state machine represented by a state-transition diagram. A state machine includes all the system states, transitions between states, and the corresponding actions. For example, in the single-server queueing system, the state could be the number of customers in the system, the transitions are the two events “arrival of a new customer” and “departure of finished customer,” and the actions are either to increase the number of customers in the system by one (when the arrival transition occurs) or decrease the number of customers in the system by one (when a departure transition occurs). There is no need to include the transition for the start of a service because the state is the number of customers in the system, which does not change when a service begins. There is a mapping between the states, transitions, and actions of a state machine and the state variables, events, and conditions and state changes of an event relationship graph. Therefore, the modeling powerful of an event relationship graph is equivalent to a state machine (or a Turing machine) (see a formal proof in Savage *et al.* [10]).

Besides graphical representations, a discrete-event can also be represented formally as a mathematical model. One example is the formalism called *Discrete event system specification* (DEVS). The DEVS formalism describes a discrete-event system by defining all the events, how the states change, how the times of different activities advance, how the events change the states and vice versa both externally and internally [11]. Another well-known discrete-event modeling formalism is the generalized semi-Markov process (GSMP). GSMP is a formal way of

describing the dynamics of a discrete-event system. It facilitates mathematical analysis of the underlying system [12]. Another representation of discrete-event systems is based on optimization models. In this representation, events are represented as decision variables, event relationships are modeled by constraints, event times are captured by the right-hand-sides of the constraints, and event scheduling (i.e., execute an event as soon as feasible) is realized by the objective function of the optimization model. The benefits of the optimization representation include using dual variables for sensitivity analysis, identifying deadlocks by examining feasibility of the optimization model, obtaining more efficient simulation models by eliminations of redundant constraints [13].

CONTINUOUS SIMULATION MODELS

Continuous simulation models simulate systems with state variables that change continuously in time. One popular type of continuous simulation is *system dynamics*. This method is suitable for systems with feedback structures and for modeling high-level of abstraction of a real system. In a system dynamics simulation model, the state of the system is represented by stocks and the rate of change in the state as flows. The stock variables accumulate all past state values and therefore, represent the current system state (e.g., $x(t)$ and $y(t)$ in the example below). The flow variables (can also be parameters) are measured per unit of time such as the changes in a state variable per second (e.g., the growth and death rates in the example below). Another type of continuous simulation models frequently used in modeling and simulating queueing systems is stochastic fluid (flow) models. Continuous simulation has been widely used in many fields, including electrical engineering, chemistry, biology, mechanical engineering, business, and so on.

One simple continuous simulation model is the Lotka-Volterra’s predator-prey model, which models the competition between two types of populations: prey and predators [1]. Let $x(t)$ and $y(t)$ denote, respectively, the number of individuals in the prey and

predator populations at time t . Each population is determined by two quantities, the *pure change rate* of the population itself and the *interaction rate* due to the interaction with the other population. The pure change rate of the prey is their growth rate in the absence of the predators (denoted by a), while the pure change rate of the predators is their death rate (or starvation rate) due to the absence of the prey (denoted by $-b$, which is negative because it is decreasing). The interaction rate of the prey is the decrease in their numbers due to the presence of the predators (denoted by $-cy(t)$, which is proportional to the number of predators) and the interaction rate of the predators is the increase in their population due to the presence of the prey (denoted by $dx(t)$, which is proportional to the number of prey).

This model assumes exponential growth (or death) in both populations in the absence of the other, that is, the prey's growth is $x'(t) = ax(t)$ and the predators' death is $y'(t) = -by(t)$. The interaction between the two populations are captured by the product of their population sizes, that is, the decrease in the prey due to the predators is $-cx(t)y(t)$ and the increase in the predators due to the prey is $dx(t)y(t)$. Combining the pure change and interaction terms for each population gives two differential equations

$$x'(t) = ax(t) - cx(t)y(t), \quad (2)$$

$$y'(t) = -by(t) + dx(t)y(t). \quad (3)$$

This simple differential-equation model can be solved exactly to obtain analytical solutions for $x(t)$ and $y(t)$. With boundary conditions and given values for all parameters, one can determine (i.e., simulate) the system state at any time t . There is no randomness in this simple model. To model randomness, one can include (e.g., add) random factors, which can also be functions of t , to above equations, for example, Gaussian noises. This will increase the complexity of the model. Indeed, simulation models of many real-world systems are so complex that no closed-form solutions can be obtained. Numerical methods, such as the Runge-Kutta method, can be used to find approximate solutions [14].

AGENT-BASED MODELS

In this section, we first discuss the connection between agent-based simulation and the two simulation approaches: discrete-event and continuous simulations. We then introduce some concepts of agent-based simulation (such as agents and interactions) and outline a general algorithm for executing an agent-based simulation model. We exemplify these concepts by using a simple agent-based simulation model.

Loosely speaking, an agent-based simulation model is a hybrid discrete-continuous simulation model with proactive, autonomous, and intelligent entities. Recall that entities in a discrete-event simulation model are rather simple with limited capabilities, and can only react to state changes. In the process-interaction queueing model with impatient customers, the customer entities cannot actively leave the system when their impatient times expire. A separated mechanism by using virtual entities is needed to trigger the departure of the impatient customers. The servers in this model are also reactive. For instance, if we model vacations or breakdown (e.g., sick), then separated mechanisms (such as vacation timers or failure timers) will be needed.

Agent-based simulation extends the capability of entities to allow autonomy and intelligence. The resulting autonomous objects (called *agents*) are able to proactively interact with other agents and the environment in which they situate. If an agent-based simulation model includes both discrete and continuous state variables, it is a hybrid discrete-continuous simulation model with proactive autonomous entities.

The popularity of agent-based simulation is driven by the increasing complexity of real-world systems and its capability of handling these complex systems. A real-world complex system often contains a large number of interacting units that are autonomous, goal-driven, and adaptive (i.e., "*agents*"). For example, a large-scale health-care network may consist of a number of units from large facilities such as hospitals, medical supply warehouses, blood banks to small service units such as ambulances,

operating rooms, and from personnel such as doctors and nurses to patients and other service providers. All these units can be considered as autonomous agents. For example, warehouses react to demands by providing inventory based on a certain rule, ambulances operate in accordance with some dispatch policies and physical mechanical rules, and patients try to intelligently select doctors. In many cases, agents, while operating based on their own strategies, cooperate or compete with each other in accordance with certain mutual rules or agreements.

It is natural to model agents as objects in a computer program and simulate their interactions to see what interaction rules lead to what consequences (i.e., emergent behavior). Mechanisms or policies can then

be enforced to discourage bad behavior and promote good ones. Emergent behavior here means arising coherent patterns of macroscopic behavior resulting from microscopic actions and interactions. This leads to the agent-based simulation approach, which has been developed rapidly over the past two decades. It has been widely used in various fields including military, biology, social science, economics, business, and so on. The theoretical basis of agent-based simulation lies mainly in *cellular automata* [15–17], *complex system modeling*, *artificial life*, and *swarm intelligence* [18,19].

The algorithm for executing an agent-based simulation model varies greatly across different agent-based platforms. A general scheme is outlined below.

Agent-Based Simulation Execution Algorithm

Initialize

Do until stop condition is satisfied

 Advance clock by a given amount of time (e.g., a tick count)

 Update all continuous state variables

 For each agent (select an agent randomly or based on a specific order)

 Perform actions: change state, communicate with other agents or environment, etc.

We now use the *Conway's Game of Life* model to illustrate the modeling of agents, their interactions, and the resulting emergent behavior. Imagine that there is a two-dimensional grid of size $n \times n$, where n is the number of rows (or columns) in the grid. Each entry of the grid lives a cell. The cells cannot move. Each cell has only two states: alive and dead. Each cell changes its state based on the following three simple rules that describe its interactions with its eight neighbors (up, down, left, right, and four diagonal cells). See the left panel of Fig. 6 for a visual description of the rules.

1. A live cell with exactly two or three live neighbors will remain alive in the next time step.
2. A dead cell with exactly three live neighbors will come to life in the next time step.

3. Otherwise, the cell will die either of loneliness or crowdedness in the next time step.

Implementing this model in a standard agent-based simulation package (such as Repast [20] or NetLogo [21]) and running it for about one hundred iterations yields a distribution of relatively stable patterns of live cells as shown in the right panel of Fig. 6. Note that the middle panel of Fig. 6 is the initial distribution of live cells.

In fact, this example is so simple that it can be considered as a cellular automaton. A cellular automaton model considers a set of cells residing in a two-dimensional lattice. Moreover, this model only includes discrete state variables and therefore can also be modeled by using the discrete-event simulation approach.

To demonstrate the flexibility of this model in arriving different emergent behaviors, we generalize the original Game of Life model

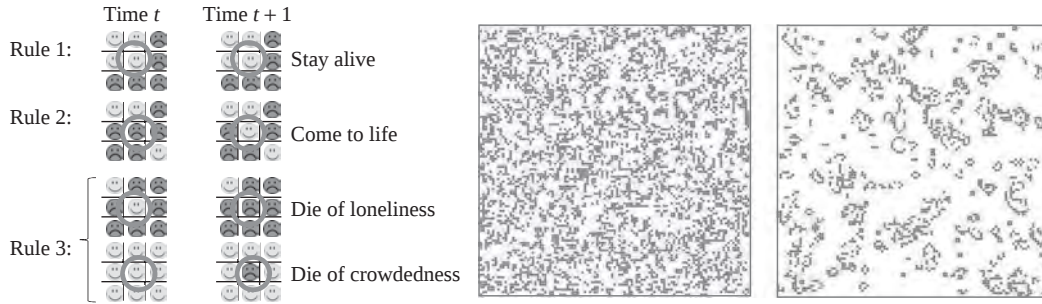

Figure 6. Agent-based simulation model of Conway's game of life.

by simply changing the number of live neighbors in Rules 1 and 2 to X , Y , and Z as defined below. To better visualize the emergent patterns, we also color the cells based on the number of live neighbors (see the legend of Fig. 7).

The variation of Conway's game of life model is as follows:

1. A live cell with the number of live neighbors between X and Y , inclusively, will remain alive in the next time step,
2. A dead cell with exactly Z live neighbors will come to life in the next time step,
3. Otherwise, the cell will die either of loneliness or crowdedness in the next time step,

where $0 \leq X, Y, Z \leq 8$ and $X \leq Y$.

This variation has a total of 288 possible combinations of rules, (X, Y, Z) . Some of them are trivial but some produce clear emergent patterns as shown in Fig. 7. These patterns also evolve in time. One can also use a sequence of multiple rules to obtain different combinations of patterns. The patterns shown in Fig. 7 are obtained by using this sequence of rules: $(0, 7, 8) \rightarrow (0, 7, 3) \rightarrow (0, 7, 6) \rightarrow (0, 7, 5) \rightarrow (0, 7, 4) \rightarrow (0, 5, 4) \rightarrow (3, 5, 4)$, where the first rule is to initialize the states of all cells to dead.

Although cellular automata are already Turing complete, agent-based simulation allows agents to have a greater degree of flexibilities and functionalities (such as learning and adaptation) and can accommodate more complicated interaction rules both between agents and agents, and between

agents and their environment. Agents can also have internal memories and perceptions to respond to outside and adjust their inside. Agent-based simulation also allows different kinds of spatial environments, such as ring, lattice, random, or maps (such as GIS maps). Agents can move freely in its environment. This makes it applicable for modeling and visualizing complex behavior in physical systems, such as simulations of traffic, evacuations, biological systems, mechanical systems, and so on.

One issue in agent-based simulation is the order in which the agents' states are updated in each time step. If one agent is updated before its neighbors are updated, then its state at the current time step can affect the states of its neighbors at this time step, otherwise, its state at the current time step will affect its neighbors in the next time step. One common practice is to randomize the updating order.

The computational requirement of the agent-based simulation execution algorithm is high because it has to loop through all agents in each time step. Methods have been proposed to avoid looping all agents, for example, only updating those agents whose state changes matter. Another approach is to employ the discrete-event simulation algorithm to advance the clock based on events and only update the continuous variables in every time step. Different hardware (such as parallel CPUs or graphics processing units—GPU) have also been used to improve the efficiency of agent-based simulation models. It has been shown that execution speed can be improved by thousands of times when using GPU [22].

Figure 7. Emergent behavior of variation of Conway's game of life model.

Monte-CARLO MODELS

Monte-Carlo simulation approach is based on repeated sampling from an algorithm, a set of equations, or a given computer model. Sampling here means two steps: (i) generate random numbers and (ii) evaluate the target values using the generated random numbers. In general, the sampling targets can be static or dynamics, continuous or discrete, or deterministic or stochastic. Sampling from a deterministic target is needed when the response space of the target is large and only a certain amount of computing budget is allocated to sample a fraction of the whole space.

The relationship between Monte-Carlo simulation and other simulations such as discrete-event or continuous simulations is subtle and depends on how one defines Monte-Carlo simulation. If one considers Monte-Carlo simulation as a static model that does not involve time or represents a system at a particular time (as discussed in the section titled "Introduction"), then Monte-Carlo simulation is a special case of other simulations that involve time. The relationship turns around if one allows the sampling target to evolve in time.

While different definitions of Monte-Carlo simulations can be found in the

literature, one popular definition is by Law (2006) in which Monte-Carlo simulation is defined as “a scheme employing random numbers...used for solving certain stochastic or deterministic problems where the passage of time plays no substantive role.” This definition is well accepted in the discrete-event simulation area as it clearly differentiates discrete-event dynamic simulation and static pure-sampling-based simulation.

Monte-Carlo simulation has various applications in physics, mathematics, and finance, such as simulating molecular dynamics, global warming impacts, earthquakes, solving diverse mathematical problems (from numerical integration to Markov chains, and from heuristics optimization algorithms to games), and evaluation and prediction (e.g., simulation of Econometrics models such as geometric Brownian motion, diffusion models, and GARCH models) [23].

CONCLUSION

This introductory article introduces basic modeling concepts in discrete-event simulation, continuous simulation, and agent-based simulation. It also highlights the relationship among these modeling approaches as well as different world views of discrete-event simulation models.

Besides these modeling approaches, new simulation modeling methods are also being proposed and developed. Classical approaches tend to focus on aspects of efficiency, easy-to-learn, and animation-friendly. New approaches are moving toward the need of an integrated simulation framework, in which modeling, analysis, and presentation are integrated. How a simulation model is created directly influences experimentations (analysis), and data collections and interpretation (presentation), which in turn affect the validity (or credibility) of the simulation model and results. Therefore, the construction of a simulation model should be tied to the corresponding analysis and presentation based on the need of the underlying simulation study.

FRITZ–JOHN AND KKT OPTIMALITY CONDITIONS FOR CONSTRAINED OPTIMIZATION

APRIL ANDREAS
Engineering and Mathematics,
McLennan Community
College, Waco, Texas

In this article, we introduce Fritz–John and Karush–Kuhn–Tucker (KKT) optimality conditions for constrained optimization, following in large part the discussion of this material in Bazaraa *et al.*[1]. We first review some critical definitions that may be already familiar and further define particular sets related to feasible and improving regions for an optimization problem, establishing some basic relationships among the same. Next, we show a simple and direct derivation of the Fritz–John optimality conditions, which when present ensure optimality of a given point $\bar{x}$. We then show how to derive the KKT conditions for optimality. Next, we provide a generalization of Fritz–John and KKT theory, with necessary and sufficient conditions for optimality, and conclude with some simple numerical examples.

DEFINITIONS

Consider an optimization problem of the form

$$\begin{aligned} \min \quad & f(x) \\ \text{subject to} \quad & g_i(x) \leq 0 \quad \forall i \in 1, \dots, m \end{aligned}$$

where f and g_i are differentiable functions, and where x is a finite-dimensional real vector.

We begin first with several definitions. Recall the definitions for convexity and concavity of $f(x)$, summarized in the table below, where each condition must hold for all feasible vectors x_1 and x_2 , $0 < \tau < 1$, to fit the related definition.

Define F at some point $\bar{x}$ as the set of all descent directions d , that is, $f(\bar{x} + \lambda d <$

$f(\bar{x}) \quad \forall \lambda \in (0, \varepsilon)$, for some ε . That is, $d \in F$ if the objective initially decreases by moving from $\bar{x}$ along direction d .

Definition	Condition
$f(x)$ is convex	$f(\tau x_1 + (1 - \tau)x_2) \leq \tau f(x_1) + (1 - \tau)f(x_2)$
$f(x)$ is strictly convex	$f(\tau x_1 + (1 - \tau)x_2) < \tau f(x_1) + (1 - \tau)f(x_2)$
$f(x)$ is concave	$f(\tau x_1 + (1 - \tau)x_2) \geq \tau f(x_1) + (1 - \tau)f(x_2)$
$f(x)$ is strictly concave	$f(\tau x_1 + (1 - \tau)x_2) > \tau f(x_1) + (1 - \tau)f(x_2)$

If we also define $F_0 = \{d : \nabla f(\bar{x})^T d < 0\}$ and define $F'_0 = \{d \neq 0 : \nabla f(\bar{x})^T d \leq 0\}$, it is clear that $F_0 \subseteq F \subseteq F'_0$. Note that $F_0 = F$ if and only if f is convex, and that $F = F'_0$ if and only if f is strictly concave.

Define G at some point $\bar{x}$ as the set of all feasible directions d , that is $\bar{x} + \lambda d$ is feasible $\forall \lambda \in (0, \varepsilon)$, for some ε .

Let all the binding constraints from $i = 1, \dots, m$ be enumerated in the set I . Now, if we also define $G_0 = \{d : \nabla g_i(\bar{x})^T d < 0 \quad \forall i \in I\}$ and $G'_0 = \{d \neq 0 : \nabla g_i(\bar{x})^T d \leq 0 \quad \forall i \in I\}$, it is also clear that $G_0 \subseteq G \subseteq G'_0$. Note that $G_0 = G$ if and only if g_i is strictly convex $\forall i \in I$, and that $G = G'_0$ if and only if g_i is concave $\forall i \in I$.

The following derivations will rely also on Gordon's lemma and Farkas' lemma, which are two theorems of the alternative. Gordon's lemma states that there exists a solution to exactly one of the following two systems:

$$\text{System I : } Ax < 0$$

$$\text{System II : } A^T y = 0, y \geq 0, y \neq 0,$$

and Farkas' lemma states that there exists a solution to exactly one of the following two systems:

$$\text{System I : } Ax \leq 0, c^T x > 0$$

$$\text{System II : } A^T y = c, y \geq 0.$$

DERIVATION OF FRITZ-JOHN OPTIMALITY CONDITIONS

With respect to the optimization problem introduced in the previous section, it is clear that if $\bar{x}$ is a local minimum, then $F \cap G = \emptyset$, since no directions are both feasible (G) and improving (F). Since $F_0 \subseteq F$ and $G_0 \subseteq G$, we can also state that $F_0 \cap G_0 = \emptyset$. If $F_0 \cap G_0 = \emptyset$ then there is no direction d such that

$$\begin{pmatrix} \nabla f(\bar{x})^T \\ \nabla g_{i_1}(\bar{x})^T \\ \nabla g_{i_2}(\bar{x})^T \\ \vdots \\ \nabla g_{i_p}(\bar{x})^T \end{pmatrix} d < \begin{pmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (1)$$

where $\nabla f(\bar{x})$ and $\nabla g_{i_1}(\bar{x}), \dots, \nabla g_{i_p}(\bar{x})$ are column vectors, and where $I = \{i_1, \dots, i_p\}$. If we let

$$A = \begin{pmatrix} \nabla f(\bar{x})^T \\ \nabla g_{i_1}(\bar{x})^T \\ \nabla g_{i_2}(\bar{x})^T \\ \vdots \\ \nabla g_{i_p}(\bar{x})^T \end{pmatrix},$$

we can then rewrite Equation (1) as $Ad < 0$. Since there is no solution to $Ad < 0$, Gordon's lemma implies that there must be a solution to $A^T u = 0$, that is,

$$(\nabla f(\bar{x}) \quad \nabla g_{i_1}(\bar{x}) \quad \dots \quad \nabla g_{i_p}(\bar{x})) \begin{pmatrix} u_0 \\ u_1 \\ \vdots \\ u_p \end{pmatrix} = 0, \quad (2)$$

for some $u \geq 0, u \neq 0$. Equation (2) can be rewritten as $u_0 \nabla f(\bar{x}) + \sum_{i=1}^m u_i \nabla g_i(\bar{x}) = 0$, where $u_0 \geq 0, u_i \geq 0 \forall i \in I, u \neq 0$.

A summary of this logic follows:
 $\bar{x}$ is a local minimum $\rightarrow$

$$F \cap G = \emptyset \rightarrow$$

$$F_0 \cap G_0 = \emptyset \leftrightarrow$$

there exists no d such that $Ad < 0 \leftrightarrow$; there is a solution to $u_0 \nabla f(\bar{x}) + \sum_{i=1}^m u_i \nabla g_i(\bar{x}) = 0$, where $u_0 \geq 0, u_i \geq 0 \forall i \in I, u \neq 0$.

We may now formally define a Fritz-John point $\bar{x}$ as one that satisfies the following conditions for some vector u .

Primal feasibility

- $\bar{x}$ is feasible

Dual feasibility

- $u_0 \nabla f(\bar{x}) + \sum_{i=1}^m u_i \nabla g_i(\bar{x}) = 0, u \geq 0, u \neq 0$

Complementary slackness

- $g_i(\bar{x})u_i = 0 \forall i = 1, \dots, m$

The implication is that if $\bar{x}$ is locally optimal, then it is a Fritz-John point, and hence the three conditions above are *necessary* conditions. There are two single-direction implication arrows in the first two lines of the logical progression. Our next task will be to work this logical progression backwards, and by this means we will derive *sufficient* Fritz-John conditions for a point to be optimal.

First, examine the statement $F \cap G = \emptyset \rightarrow F_0 \cap G_0 = \emptyset$. The reverse statement is true when $F_0 = F$ and $G_0 = G$. We noted in the definitions section that $F_0 = F$ if and only if f is convex and $G_0 = G$ if and only if g_i is strictly convex $\forall i \in I$. If we make these assumptions, we can conclude that $F_0 \cap G_0 = \emptyset \rightarrow F \cap G = \emptyset$.

Next, examine the statement that $\bar{x}$ is a local minimum $\rightarrow F \cap G = \emptyset$. We cannot assume that $F \cap G = \emptyset$ implies that $\bar{x}$ is a local minimum, because we may be ignoring nonlinear feasible directions. However, if we have assumed that g_i is strictly convex $\forall i \in I$, then the feasible region is locally convex and we can restrict our attention to straight-line directions. By assuming a locally convex feasible region,

we can conclude that $F \cap G = \emptyset \rightarrow \bar{x}$ is a local minimum. Therefore, if $f(x)$ is convex and all binding constraints are strictly convex, then a Fritz–John point is a local minimum.

DERIVATION OF KKT OPTIMALITY CONDITIONS

We begin our discussion of KKT conditions by following some of the same logic used for deriving the Fritz–John conditions. Again, note that if $\bar{x}$ is a local minimum, then $F \cap G = \emptyset$, and since $F_0 \subseteq F$, we can also state that $F_0 \cap G = \emptyset$. If we assume that g_i is concave $\forall i \in I$, then $G = G'_0$, and we can conclude that $F_0 \cap G'_0 = \emptyset$. Therefore, there is no direction d such that

$$\nabla f(\bar{x})^T d < 0 \text{ and } \nabla g_i(\bar{x})^T d \leq 0 \forall i \in I.$$

Writing the first inequality as $-\nabla f(\bar{x})^T d > 0$, we can employ Farkas' lemma to guarantee that there exists a vector $u \geq 0$ such that

$$\nabla g_i(\bar{x})u_i = -\nabla f(\bar{x})^T \forall i \in I.$$

We can rewrite the above conditions as the following:

$$\begin{aligned} \sum_{i=1}^m u_i \nabla g_i(\bar{x}) &= -\nabla f(\bar{x}) \\ u_i &\geq 0, i \in 1, \dots, m, \end{aligned}$$

which is equivalent to the Fritz–John points described above when $u_0 = 1$.

We now summarize this logic as follows:
 $\bar{x}$ is a local minimum $\rightarrow$

$$\begin{aligned} F \cap G &= \emptyset \rightarrow \\ F_0 \cap G &= \emptyset \leftarrow \\ F_0 \cap G'_0 &= \emptyset \leftrightarrow \end{aligned}$$

there exists no d such that $\nabla g_i(\bar{x})^T d \leq 0 \forall i \in I$ and $-\nabla f(\bar{x})^T d > 0 \leftrightarrow$ there is a vector $u \geq 0$ such that $\nabla g_i(\bar{x})u_i = -\nabla f(\bar{x})^T \forall i \in I$.

The third arrow is bidirectional if, for instance, g_i is concave $\forall i \in I$.

Formally, we say that $\bar{x}$ is a KKT point if there exists a vector u such that the following conditions hold.

Primal feasibility

- $\bar{x}$ is feasible

Dual feasibility

- $\nabla f(\bar{x}) + \sum_{i=1}^m u_i \nabla g_i(\bar{x}) = 0, u \geq 0$

Complementary slackness

- $g_i(\bar{x})u_i = 0 \forall i = 1, \dots, m$

We have shown that a local minimum is a KKT point if constraints are concave. Constraint concavity is just one possible constraint qualification under which KKT conditions are necessary for optimality; see the article titled **Constraint Qualifications** for an expanded discussion. We now pursue this logic backwards. If KKT conditions are met, then we can state that $F_0 \cap G = \emptyset$. If we also assume that f is convex, then $F_0 = F$ and we can state that $F \cap G = \emptyset$. Finally, if we assume that the feasible region is locally convex, then $F \cap G = \emptyset$ implies that $\bar{x}$ is a local minimum. Therefore, a KKT point is a local minimum if f is convex and all binding constraints are convex. Note that if all constraints are convex, then a KKT point is a global optimum.

COMPARISON OF FRITZ–JOHN AND KKT POINTS

In the previous discussion, we identified a KKT point $\bar{x}$ as a Fritz–John point where $u_0 = 1$. That is, all KKT points are Fritz–John points, but not all Fritz–John points are KKT points.

Recall that if $\bar{x}$ is a Fritz–John point, the following dual feasibility condition must hold true:

$$\sum_{i=1}^m u_i \nabla g_i(\bar{x}) = -u_0 \nabla f(\bar{x}), u \geq 0, u \neq 0.$$

There are two options for u_0 : either $u_0 = 0$ or $u_0 \neq 0$. In the former case, we can scale the dual solution by dividing each element of u by u_0 to obtain a vector in which $u_0 = 1$,

which in turn proves that $\bar{x}$ is in fact a KKT point.

If $u_0 = 0$, then the dual feasibility condition becomes

$$\sum_{i=1}^m u_i \nabla g_i(\bar{x}) = 0, u \geq 0, u \neq 0. \quad (3)$$

Equation (3) implies that any one vector $\nabla g_i(\bar{x})$ can be written as a linear combination of the remaining vectors; that is, vectors $\nabla g_i(\bar{x})$ are linearly dependent.

Suppose however that the binding constraint gradients are known to be linearly independent. This removes the possibility that u_0 could equal zero, leaving that u_0 must be greater than 0, and hence that the Fritz-John conditions are equivalent to the KKT conditions. In this case, the KKT conditions are necessary for local optimality.

FURTHER GENERALIZATION

Now consider the following optimization problem, which includes a set of equality constraints:

$$\begin{aligned} \min \quad & f(x) \\ \text{subject to} \quad & g_i(x) \leq 0 \quad \forall i = 1, \dots, m \\ & h_i(x) = 0 \quad \forall i = 1, \dots, l \end{aligned}$$

where f, g_i , and h_i are differentiable functions. We can expand the definition of Fritz-John points for these problems to include any point $\bar{x}$ such that the following conditions hold.

Primal feasibility

- $\bar{x}$ is feasible

Dual feasibility

- $u_0 \nabla f(\bar{x}) + \sum_{i=1}^m u_i \nabla g_i(\bar{x}) + \sum_{i=1}^l v_i \nabla h_i(\bar{x}) = 0, u \geq 0, u \neq 0, v$ unrestricted

Complementary slackness

- $g_i(\bar{x})u_i = 0 \quad \forall i = 1, \dots, m$

Note that if we simply replace each equality constraint $h_i(x) = 0$ with two inequalities $h_i(x) \leq 0$ and $h_i(x) \geq 0$, then every feasible $\bar{x}$ solution is a Fritz-John point, thus making the Fritz-John conditions extremely weak.

We summarize the relationship with Fritz-John points and local optima below:

- If $\bar{x}$ is a local minimum, then it is a Fritz-John point.
- If $\bar{x}$ is a Fritz-John point, it is a local minimum if all of the following conditions are met:
 - f is convex;
 - binding $g_i(\bar{x})$ are strictly convex;
 - h_i are affine $\forall i = 1, \dots, l$;
 - $\nabla h_i(\bar{x})$ are linearly independent.

Similarly, we can expand the definition of KKT points to include any point $\bar{x}$ such that the following conditions hold.

Primal feasibility

- $\bar{x}$ is feasible

Dual feasibility

- $\nabla f(\bar{x}) + \sum_{i=1}^m u_i \nabla g_i(\bar{x}) + \sum_{i=1}^l v_i \nabla h_i(\bar{x}) = 0, u \geq 0, u \neq 0, v$ unrestricted

Complementary slackness

- $g_i(\bar{x})u_i = 0 \quad \forall i = 1, \dots, m$

We summarize the relationship with optimality below:

- *Necessary.* If $\bar{x}$ is a local minimum, then it is a KKT point if
 - binding $\nabla g_i(\bar{x})$ are linearly independent;
 - all $\nabla h_i(\bar{x})$ are linearly independent.
- *Sufficient.* If $\bar{x}$ is a KKT point, then it is a local minimum if
 - f is convex;
 - binding $g_i(\bar{x})$ are convex;
 - $h_i(\bar{x})$ are convex if $v_i > 0$, concave if $v_i < 0$, and unrestricted if $v_i = 0$.

Also, as an alternative to the necessary conditions above, if all f_i are concave and all h_i are affine, then a local minimum must be a KKT point.

EXAMPLE USING FRITZ–JOHN THEORY

Consider the following optimization problem:

$$\begin{aligned} \min \quad & x_1 + x_2 \\ \text{subject to} \quad & (x_1 - 1)^2 + (x_2 - 1)^2 \geq 2 \\ & x_1 \geq 0, x_2 \geq 0 \end{aligned}$$

Since Fritz–John conditions are necessary for local optimality, and since this problem is clearly bounded (and an optimal solution exists), we can determine an optimal solution by finding all the Fritz–John points, and choosing one having the smallest objective as an optimal solution. First, we rewrite the problem as follows:

$$\begin{aligned} \min \quad & x_1 + x_2 \\ \text{subject to} \quad & -(x_1 - 1)^2 - (x_2 - 1)^2 \leq -2 \\ & -x_1 \leq 0 \\ & -x_2 \leq 0 \end{aligned}$$

we then establish the following conditions.

Primal feasibility

$$\begin{aligned} \bullet \quad & (x_1 - 1)^2 + (x_2 - 1)^2 \geq 2 \\ & x_1 \geq 0, x_2 \geq 0 \end{aligned}$$

Dual feasibility

$$\begin{aligned} \bullet \quad & \begin{pmatrix} -2(\bar{x}_1 - 1) \\ -2(\bar{x}_2 - 1) \end{pmatrix} u_1 + \begin{pmatrix} -1 \\ 0 \end{pmatrix} u_2 \\ & + \begin{pmatrix} 0 \\ -1 \end{pmatrix} u_3 = \begin{pmatrix} -1 \\ -1 \end{pmatrix} u_0 \end{aligned}$$

Complementary slackness

$$\begin{aligned} \bullet \quad & u_1(-(x_1 - 1)^2 - (x_2 - 1)^2 + 2) = 0 \\ & u_2(-x_1) = 0 \\ & u_3(-x_2) = 0 \end{aligned}$$

Again, there are two options for u_0 : either $u_0 = 0$ or $u_0 > 0$ (with $u_0 = 1$ without loss of generality in the second case). If $u_0 = 0$, we must have $u_1 > 0$ since $\nabla g_2(\bar{x})$ and $\nabla g_3(\bar{x})$ are linearly independent. Since $u_1 > 0$, constraint 1 must be binding:

$$(\bar{x}_1 - 1)^2 + (\bar{x}_2 - 1)^2 = 2.$$

Since $x_1 = x_2 = 1$ is infeasible, we know that $\nabla g_1(\bar{x}) \neq 0$ for any feasible $\bar{x}$, and so at least

one of u_2 and u_3 must be positive. First, suppose that $u_2 > 0$, and so constraint 2 must be also binding, which implies that $\bar{x}_1 = 0$. Therefore

$$(0 - 1)^2 + (\bar{x}_2 - 1)^2 = 2 \rightarrow \bar{x}_2 = 0 \text{ or } \bar{x}_2 = 2.$$

Now, we determine whether $(\bar{x}_1, \bar{x}_2) = (0, 0)$ or $(\bar{x}_1, \bar{x}_2) = (0, 2)$ is a Fritz–John point:

$$\begin{aligned} (\bar{x}_1, \bar{x}_2) = (0, 0) : \\ \begin{pmatrix} 2 \\ 2 \end{pmatrix} u_1 + \begin{pmatrix} -1 \\ 0 \end{pmatrix} u_2 + \begin{pmatrix} 0 \\ -1 \end{pmatrix} u_3 &= \begin{pmatrix} 0 \\ 0 \end{pmatrix} \\ \rightarrow u_2 = 2u_1, u_3 = 2u_1 \end{aligned}$$

Choosing u_1 to be any positive value, we have that $(0, 0)$ is a Fritz–John point.

$$(\bar{x}_1, \bar{x}_2) = (0, 2) :$$

$$\begin{aligned} \begin{pmatrix} 2 \\ -2 \end{pmatrix} u_1 + \begin{pmatrix} -1 \\ 0 \end{pmatrix} u_2 + \begin{pmatrix} 0 \\ -1 \end{pmatrix} u_3 \\ = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \rightarrow \text{has no solution} \end{aligned}$$

Therefore, $(0, 2)$ is not a Fritz–John point when $u_0 = 0$.

The case of $u_3 > 0$ is symmetric, and does not reveal any further Fritz–John points. Next, if $u_0 = 1$, we have the following:

$$\begin{aligned} \begin{pmatrix} -2\bar{x}_1 + 2 \\ -2\bar{x}_1 + 2 \end{pmatrix} u_1 + \begin{pmatrix} -1 \\ 0 \end{pmatrix} u_2 + \begin{pmatrix} 0 \\ -1 \end{pmatrix} u_3 \\ = \begin{pmatrix} -1 \\ -1 \end{pmatrix} \end{aligned}$$

If $u_1 = 0$, then $u_2 = u_3 = 1$ and g_2 and g_3 must be binding, so we again have the point $(\bar{x}_1, \bar{x}_2) = (0, 0)$. Continuing this process, we compute the following four points:

- $\bar{x} = (0, 0)$ —all three constraints are binding: $f(\bar{x}) = 0$;
- $\bar{x} = (0, 2)$ —constraints 1 and 2 are binding: $f(\bar{x}) = 2$;
- $\bar{x} = (2, 0)$ —constraints 1 and 3 are binding: $f(\bar{x}) = 2$;
- $\bar{x} = (2, 2)$ —constraint 1 is binding: $f(\bar{x}) = 4$.

Since our objective is of the minimization sense, $\bar{x} = (0, 0)$ is optimal.

EXAMPLE USING KKT THEORY

Consider the following optimization problem:

$$\begin{aligned} \min \quad & -x_1 \\ \text{subject to} \quad & x_1^2 + x_2 \leq 4 \\ & x_1 + x_2 = 2 \end{aligned}$$

We first show that $\bar{x} = (2, 0)$ is a KKT point. Observe that $g(x) = x_1^2 + x_2 - 4$ and $h(x) = x_1 + x_2 - 2$. To show that $(2, 0)$ is a KKT point, we must show that it satisfies all primal feasibility, dual feasibility, and complementary slackness conditions.

Primal feasibility

- $x_1^2 + x_2 \leq 4$
 $x_1 + x_2 = 2$

Dual feasibility

- $\begin{pmatrix} -1 \\ 0 \end{pmatrix} + \begin{pmatrix} 2x_1 \\ 1 \end{pmatrix} u + \begin{pmatrix} 1 \\ 1 \end{pmatrix} v = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$

Complementary slackness

- $(x_1^2 + x_2 - 4)u = 0$

We can satisfy these conditions by setting $\bar{x} = (2, 0)$, $u = 1/3$, and $v = -1/3$; therefore, $\bar{x} = (2, 0)$ is a KKT point.

Since f is convex, the binding $g_i(\bar{x})$ are convex, and $h_i(\bar{x})$ are affine and linearly independent, we can conclude that $\bar{x}$ is a KKT point and is locally optimal. Furthermore, since the feasible region is convex (in addition to having a convex objective function), a local optimal solution is a global optimal solution, and so $\bar{x} = (2, 0)$ is globally optimal.

FUZZY MEASURES AND INTEGRALS IN MULTICRITERIA DECISION ANALYSIS

MICHEL GRABISCH
University of Paris I, Paris School
of Economics, Paris, France

INTRODUCTION

Most of the methods in multicriteria decision making (MCDM) use the weighted arithmetic mean (WAM) (weighted sum) when criteria have to be aggregated. This simple aggregation function, used from the ancient Greeks, is universally used and has the advantage of simplicity and readability, in the sense that any decision maker without special knowledge can understand the meaning of its parameters, namely the weights on the criteria. However, the drawbacks of the weighted sum have been pointed out many times: for instance, its sensitivity to extreme values and, more importantly, its inability to explore the concave parts of the Pareto frontier in multiobjective optimization problems. On a more practical side, the weighted sum is unable to translate behaviors in aggregation such as favor high scores; focus on weak points; and eliminate alternative if criterion 3 is not well satisfied; if criteria 1 and 2 are satisfied, do not overestimate their importance. The first two examples in the previous list are still relatively simple, as they can be handled by a weighted sum on the ordered list of scores in increasing order: this is called the ordered weighted average (OWA), and it contains, as particular cases, the median, the minimum, and the maximum. However, the last two examples are more complex and cannot be treated, neither by the weighted sum nor by an OWA. They are typical examples of *interaction* between criteria. Interaction means that the way the score on a criterion is handled depends on the value of the scores on the other criteria. A typical example

given in Ref. 1 is the following: suppose that some students are evaluated on three topics, which are mathematics, physics, and literature, with an emphasis on scientific topics. There is some interaction between mathematics and physics in the sense that, as usually students good at maths are also good at physics and vice versa, a good mark in both math and physics should not be overestimated with respect to literature. On the contrary, as scientific topics are more important, bad marks in both mathematics and physics become very important. The existence of interaction phenomena, as well as the inability of the weighted sum to represent them, has been recognized from a long time ago, and the absence of an adequate tool to consider them has provoked the appearance of the following general rule for the practitioner: *choose/define criteria so that they are independent (no interaction)*. Obviously, this rule cannot always be applied, or leads to excessive simplification.

The appearance of the Choquet integral in MCDM has permitted to solve this problem, and has brought a precise definition of what interaction is. The Choquet integral not only generalizes both the weighted sum and the OWA but also can model the examples of interaction described earlier. So far, many theoretical studies and real applications have been done (see the overviews [1–3] and [4, Chapter 5] for further references and details).

FUZZY MEASURES AND INTEGRALS

We consider a set of criteria $N = \{1, \dots, n\}$, and denote the set of its subsets by 2^N . An alternative is an element of $X = X_1 \times \dots \times X_n$, where X_i is the set of values for attribute i . We write $x = (x_1, \dots, x_n)$ for $x \in X$. We make the assumption that the utility functions $u_i : X_i \rightarrow \mathbb{R}$ have been determined, up to a positive affine transformation.

A *fuzzy measure* [5] or *capacity* [6] on N is a mapping $\mu : 2^N \rightarrow [0, 1]$ satisfying the following two conditions:

1. $\mu(\emptyset) = 0$, $\mu(N) = 1$.
2. $A \subseteq B$ implies $\mu(A) \leq \mu(B)$ (monotonicity).

In applications in MCDM, $\mu(A)$ is often interpreted as the *weight of importance* of the group or coalition $A \subseteq N$. This is, however, an imprecise statement, and it should be interpreted in a more rigorous way as follows. Suppose that for each criterion $i \in N$ there exist two levels with an absolute meaning, for example, a *neutral level*, denoted by $\mathbf{0}_i$, and a *satisfactory level*, denoted by $\mathbf{1}_i$ (like in the MACBETH methodology [7]). These levels are elements of X_i , and represent, respectively, a level that is neither good nor bad and a level that would make the decision maker totally satisfied if he or she could obtain it. Alternatively, the neutral level can be replaced by the *unsatisfactory level*, which is a level that is not acceptable by the decision maker. We set for convenience $u_i(\mathbf{1}_i) = 1$ and $u_i(\mathbf{0}_i) = 0$ for all $i \in N$. We consider now for any subset $A \subseteq N$ the *binary alternative* $(\mathbf{1}_A, \mathbf{0}_{-A})$, whose coordinates are $\mathbf{1}_i$ for all $i \in A$, and $\mathbf{0}_i$ otherwise. This alternative is satisfactory for all criteria $i \in A$ and neutral (or unsatisfactory) otherwise. Then, $\mu(A)$ is interpreted as the overall evaluation of $(\mathbf{1}_A, \mathbf{0}_{-A})$.

Under this interpretation, the axioms defining a fuzzy measure are natural: the overall evaluation of an alternative being neutral (or unsatisfactory) for every criterion should be 0, and its evaluation should be 1 if all criteria are satisfactory. Moreover, turning one criterion on the neutral level to a satisfactory level cannot decrease the overall evaluation (monotonicity condition).

In summary, a fuzzy measure determines the evaluation of every binary alternative. It remains to determine the evaluation of any other alternative. This is done using the *Choquet integral* [6], defined as follows. Consider an alternative $x = (x_1, \dots, x_n)$ and the vector $u(x) = [u_1(x_1), \dots, u_n(x_n)]$ of its values for the utility functions. We call $u_i(x_i)$ the *score* of x with respect to criterion i , and we denote it by a_i if there is no ambiguity. Rearrange the criteria so that $a_1 \leq a_2 \leq \dots \leq a_n$. Then, the Choquet integral of $u(x) = (a_1, \dots, a_n)$, provided all components a_i are nonnegative, is

computed as follows:

$$\begin{aligned} \mathcal{C}_\mu(a_1, \dots, a_n) \\ = a_1 \underbrace{\mu(N)}_{=1} + \sum_{i=2}^n (a_i - a_{i-1}) \mu(\{i, \dots, n\}), \\ (a_1, \dots, a_n \geq 0) \end{aligned} \quad (1)$$

or equivalently

$$\begin{aligned} \mathcal{C}_\mu(a_1, \dots, a_n) \\ = \sum_{i=1}^{n-1} a_i (\mu(\{i, \dots, n\}) \\ - \mu(\{i+1, \dots, n\})) + a_n \mu(\{n\}). \end{aligned} \quad (2)$$

Example 1 Consider $N = \{1, 2, 3\}$ and the fuzzy measure μ defined in the following table

A	$\emptyset$	{1}	{2}	{3}	{1, 2}	{1, 3}	{2, 3}	N
$\mu(A)$	0	0.2	0.2	0.4	0.5	0.6	0.7	1

Consider now the vector $u(x) = (3, 1, 6)$. Criteria should be first rearranged in the following order: 2, 1, 3, as $u_2(x_2) < u_1(x_1) < u_3(x_3)$. Then, using Equation (1), the Choquet integral is computed as follows:

$$\begin{aligned} \mathcal{C}_\mu(u(x)) &= 1 \times 1 + (3 - 1) \times \mu(\{1, 3\}) \\ &\quad + (6 - 3) \times \mu(\{3\}) \\ &= 1 + 2 \times 0.6 + 3 \times 0.4 = 3.4 \end{aligned} \quad (3)$$

Thus, the overall evaluation of x is 3.4. Observe that this value lies in $[1, 6]$, the interval of minimal and maximal utility values on the criteria.

Formula (2) clearly shows that the Choquet integral is a kind of weighted sum, the weights being $\mu(\{i, \dots, n\}) - \mu(\{i+1, \dots, n\})$. However, be careful that these weights depend on x , as criteria must be first reordered to get an increasing sequence of scores. Hence, precisely, as there are n possible orderings, the Choquet integral is an assembling of $n!$ weighted sums, each for a specific order of criteria (and this explains why the Choquet integral can model interaction). It can be proved that the

Choquet integral is nevertheless continuous. Other important properties are:

1. $C_\mu(u(\mathbf{1}_A, \mathbf{0}_{-A})) = \mu(A)$, for all $A \subseteq N$;
2. $C_\mu(\alpha u(x)) = \alpha C_\mu(u(x))$ for all $\alpha > 0$;
3. $u_i(x_i) \leq u_i(x'_i)$ for $i = 1, \dots, n$ implies $C_\mu(u(x)) \leq C_\mu(u(x'))$;
4. $\min_{i=1}^n u_i(x_i) \leq C_\mu(u(x)) \leq \max_{i=1}^n u_i(x_i)$.

The first property says that the Choquet integral extends the overall evaluation provided by the fuzzy measure. The second one says that the Choquet integral is compatible with a ratio scale. The third one says that an increase of the scores cannot lead to a decrease of the overall evaluation. The last one says that the overall evaluation is comprised between the minimum and the maximum of all scores. The two last properties imply *idempotency*, that is, $C_\mu(a, a, \dots, a) = a$ for any $a \in \mathbb{R}_+$.

So far, the Choquet integral is defined for nonnegative arguments, preventing it to be used with interval scales. In order to extend it to any real-valued argument, there are two possibilities. The first one is called the *symmetric integral*, denoted by $\check{C}_\mu$. Its name is due to the fact that $\check{C}_\mu(-u(x)) = -\check{C}_\mu(u(x))$, and it is compatible with ratio scales. However, it is not compatible with interval scales, as it is not invariant to positive affine transformations: $\check{C}_\mu(\alpha u(x) + \beta) \neq \alpha \check{C}_\mu(u(x)) + \beta$ in general, for $\alpha > 0$ and $\beta \in \mathbb{R}$. Its expression is, using the notation $u(x) = (a_1, \dots, a_n)$:

$$\begin{aligned} \check{C}_\mu(a_1, \dots, a_n) &= \sum_{i=1}^{p-1} (a_i - a_{i+1}) \mu(\{1, \dots, i\}) \\ &\quad + a_p \mu(\{1, \dots, p\}) + a_{p+1} \mu(\{p+1, \dots, n\}) \\ &\quad + \sum_{i=p+2}^n (a_i - a_{i-1}) \mu(\{i, \dots, n\}), \end{aligned}$$

having rearranged the criteria, so that $a_1 \leq \dots \leq a_p < 0 \leq a_{p+1} \leq \dots \leq a_n$.

The second possibility is called the *asymmetric integral*, and its definition merely amounts to keep the same formula (1) for $(a_1, \dots, a_n) \in \mathbb{R}^n$. The asymmetric integral is invariant to positive affine transformations and is, therefore, compatible with interval scales.

RELATION WITH OTHER AGGREGATION FUNCTIONS

The Choquet integral contains, as particular case, two important families of aggregation functions: the weighted sum (WAM) and the OWA [8]. We recall their definitions:

$$\begin{aligned} \text{WAM}(a_1, \dots, a_n) &= \sum_{i=1}^n w_i a_i \\ \text{OWA}(a_1, \dots, a_n) &= \sum_{i=1}^n w_i a_{(i)}, \end{aligned}$$

where $(a_{(1)}, \dots, a_{(n)})$ is the vector of scores rearranged in nondecreasing order, that is, $a_{(1)} \leq \dots \leq a_{(n)}$, and $w_1, \dots, w_n$ are weights in $[0, 1]$. We recall that OWA contains, as particular case, the arithmetic mean (with $w_1 = w_2 = \dots = w_n = \frac{1}{n}$), the minimum ($w_1 = 1, w_2 = \dots = w_n = 0$), the maximum ($w_1 = \dots = w_{n-1} = 0, w_n = 1$), the median, and every order statistic. We stress the fact that the weights in OWA are not weights on criteria, but weights on the rank of the scores. Hence, high values for weights with low (respectively, high) indices indicate that the OWA focuses on the smallest (respectively, greatest) scores obtained, that is, it has a conjunctive (respectively, disjunctive) behavior.

The WAM is recovered with an additive fuzzy measure, whereas the OWA is recovered with a symmetric fuzzy measure [9]. We define these terms below.

An *additive fuzzy measure* μ satisfies $\mu(A) = \sum_{i \in A} \mu(\{i\})$ for every $A \subseteq N$. It is then easy to see that the Choquet integral reduces to the WAM with $w_i = \mu(\{i\})$, for $i = 1, \dots, n$. A *symmetric fuzzy measure* μ satisfies $\mu(A) = \mu(B)$ whenever $|A| = |B|$, that is, μ depends only on the cardinality of the subsets. Letting $m_i = \mu(A)$ with $|A| = i$, we obtain that the Choquet integral reduces to an OWA with $w_i = m_{n-i+1} - m_{n-i}$, $i = 2, \dots, n$, and $w_1 = 1 - \sum_{i=2}^n w_i$.

This shows the versatility of the Choquet integral, which is able to consider both importance of criteria and importance of ranks. In particular, it can be more or less disjunctive or conjunctive.

SHAPLEY VALUE AND INTERACTION INDICES

The versatility of the Choquet integral is hindered by its exponential complexity. Indeed, the size of the model is in $O(2^n)$, which makes its use impossible for high values of n , and render its interpretation nearly impossible for the decision maker. Therefore, one needs some tool to interpret fuzzy measures, and also submodels of polynomial size. This section focuses on the first point, whereas the second one will be addressed in the next section.

The most popular tool in MCDM being the weighted sum, decision makers are used to deal with weights of importance for criteria. The Choquet integral being much more complex than a weighted sum, is there some similar notion to importance weights? An adequate answer to this question comes from cooperative game theory, through the notion of Shapley value [10, 11]. As μ quantifies the overall score of alternatives being satisfactory on some set of criteria, a criterion i should be said to be important; if whenever i enters a group of criteria A , the difference $\mu(A \cup i) - \mu(A)$ is high. The *Shapley importance index* $\phi_i(\mu)$ for criterion i is a weighted average of this difference taken over all possible $A \subseteq N \setminus i$:

$$\phi_i(\mu) = \sum_{A \subseteq N \setminus i} \frac{|A|!(n - |A| - 1)!}{n!} \times (\mu(A \cup i) - \mu(A)),$$

and the vector $(\phi_1(\mu), \dots, \phi_n(\mu))$ is called the *Shapley value* of μ . The weights in the average ensure that $\sum_{i=1}^n \phi_i(\mu) = 1$ and invariance to permutations on N . Also, $\phi_i(\mu) \geq 0$; therefore, the coefficients $\phi_1(\mu), \dots, \phi_n(\mu)$ act like weights of importance in a weighted sum.

The Shapley value offers a simple summary of the fuzzy measure μ , but is by no means a substitute to it; that is, infinitely many fuzzy measures have the same Shapley value. We need, therefore, some other quantity to enrich the summary. This is brought by the *interaction index*, a notion that is intuitively appealing in MCDM. Let us first consider two criteria i, j . By a *positive interaction* or *synergy* between i and j , we mean

that the satisfaction of both criteria is much more valuable than the satisfaction of them separately. We may say that they are *complementary*. This is translated quantitatively as follows, taking any set $A \subseteq N \setminus \{i, j\}$:

$$\begin{aligned} \mu(A \cup \{i, j\}) - \mu(A) &\geq (\mu(A \cup i) - \mu(A)) \\ &\quad + (\mu(A \cup j) - \mu(A)), \end{aligned}$$

which can be rewritten as

$$\mu(A \cup \{i, j\}) - \mu(A \cup i) - \mu(A \cup j) + \mu(A) \geq 0.$$

Similarly, a *negative interaction* or *synergy* between i and j means that the satisfaction of both is not that better than the satisfaction of one of them, leading to the reverse inequality; and in this case, we may say that they are *redundant* or *substitutable*. The case of equality means that the added value by both criteria is exactly the sum of the individual added values, hence there is no interaction between i and j . The *interaction index* $I_{ij}(\mu)$ [12] is obtained by taking a weighted average of the above expression for all possible groups $A \subseteq N \setminus \{i, j\}$:

$$\begin{aligned} I_{ij}(\mu) &= \sum_{A \subseteq N \setminus \{i, j\}} \frac{|A|!(n - |A| - 2)!}{(n - 1)!} \\ &\quad \times (\mu(A \cup \{i, j\}) - \mu(A \cup i) - \mu(A \cup j) + \mu(A)). \end{aligned}$$

Note that the weights are similar to those of the Shapley value.

The Shapley value together with the interaction indices for all pairs $i, j \in N$ gives a good summary of the fuzzy measure μ , although still not complete. It is possible to define interaction indices for more than two criteria. The general definition for a group of criteria $B \subseteq N$ is given as follows [13]:

$$\begin{aligned} I_B(\mu) &= \sum_{A \subseteq N \setminus B} \left(\frac{|A|!(n - |A| - |B|)!}{(n - |B| + 1)!} \right. \\ &\quad \left. \times \sum_{K \subseteq B} (-1)^{|B \setminus K|} \mu(A \cup K) \right). \end{aligned}$$

Note that the Shapley value is a particular case of it when $B = \{i\}$, $i \in N$. It can be

shown that the set of 2^n interaction indices $I_B(\mu)$ for $B \subseteq N$ is an exact representation of μ , in the sense that there is a one-to-one correspondence between them.

Example 2 Taking again the fuzzy measure given in Example 1, we find for the interaction indices and Shapley value:

$$\begin{aligned}
 \phi_1(\mu) &= \frac{1}{3}(0.2 - 0) + \frac{1}{6}(0.5 - 0.2) \\
 &\quad + \frac{1}{6}(0.6 - 0.4) + \frac{1}{3}(1 - 0.7) = 0.25 \\
 \phi_2(\mu) &= \frac{1}{3}(0.2) + \frac{1}{6}(0.3) + \frac{1}{6}(0.3) \\
 &\quad + \frac{1}{3}(0.4) = 0.3 \\
 \phi_3(\mu) &= \frac{1}{3}(0.4) + \frac{1}{6}(0.4) + \frac{1}{6}(0.5) \\
 &\quad + \frac{1}{3}(0.5) = 0.45 \\
 I_{12}(\mu) &= \frac{1}{2}(0.5 - 0.2 - 0.2 + 0) \\
 &\quad + \frac{1}{2}(1 - 0.6 - 0.7 + 0.4) = 0.1 \\
 I_{13}(\mu) &= \frac{1}{2}(0.6 - 0.2 - 0.4 + 0) \\
 &\quad + \frac{1}{2}(1 - 0.5 - 0.7 + 0.2) = 0 \\
 I_{23}(\mu) &= \frac{1}{2}(0.7 - 0.2 - 0.4 + 0) \\
 &\quad + \frac{1}{2}(1 - 0.5 - 0.6 + 0.2) = 0.1 \\
 I_{123}(\mu) &= 1 - 0.5 - 0.6 - 0.7 + 0.2 + 0.2 \\
 &\quad + 0.4 - 0 = 0.
 \end{aligned}$$

One sees that criterion 3 is the most important, criteria 1 and 3 are independent, and there is a slight complementarity between criteria 1 and 2, and between 2 and 3.

K-ADDITIVE FUZZY MEASURES

The main advantage of the representation of a fuzzy measure μ with interaction indices is that it gives a clear meaning to μ : the Shapley value expresses the importance of

criteria, the interaction index for pairs of criteria expresses when they are complementary or redundant, and so on. However, the interpretation of $I_B(\mu)$ is less and less clear as the size of B grows: it seems hardly possible to have a clear view of what expresses an interaction index for four criteria. This suggests that one should truncate the representation up to some level. We call *k-additive fuzzy measure* [13] a fuzzy measure for which the interaction indices are zero for any group of criteria of size greater than k . Hence, a 1-additive measure reduces to a vector of importance weights, and is, therefore, equivalent to an additive fuzzy measure. In this case, we know that the Choquet integral is merely a weighted sum. More interesting is a 2-additive fuzzy measure, as complementarity and redundancy within pairs of criteria can be expressed. It can be shown that the Choquet integral takes the following particular form [14]:

$$\begin{aligned}
 C_\mu(a_1, \dots, a_n) &= \sum_{i,j: I_{ij} > 0} (a_i \wedge a_j) I_{ij} + \sum_{i,j: I_{ij} < 0} (a_i \vee a_j) |I_{ij}| \\
 &\quad + \sum_{i \in N} a_i \left(\phi_i - \frac{1}{2} \sum_{j \neq i} |I_{ij}| \right), \quad (5)
 \end{aligned}$$

where $\wedge$ and $\vee$ stand for minimum and maximum, respectively, and we have omitted μ in $I_{ij}(\mu)$ and $\phi_i(\mu)$. This expression offers two important advantages:

1. It gives a clear meaning to the interaction index in terms of aggregation behavior. A positive interaction between i and j implies a conjunctive aggregation (*both* criteria must be satisfied), whereas a negative interaction implies a disjunctive behavior (it is enough to satisfy one of the criteria). In addition, one can see that the Shapley value indeed acts like a weight of importance in a weighted sum; however, its effect on criterion i is diminished by the sum of interaction indices pertaining to i . It follows that if criterion i has no interaction (is independent) with the other criteria,

it appears only in the linear part of the Choquet integral with weight ϕ_i .

2. The Choquet integral is a sum of terms being a minimum, a maximum, or a monomial of degree 1. It can be shown that all coefficients of these terms are nonnegative; moreover, they sum up to 1: in short, Equation (5) is a convex combination of terms representing elementary behaviors in decision making, disjunction and conjunction of two criteria, and dictators. All these local behaviors can be put in a pie chart, which offers a very clear view for the decision maker.

Finally, observe that the 2-additive model is in $O(n^2)$, as the number of free coefficients defining a 2-additive fuzzy measure is $n - 1 + \binom{n}{2} = \frac{n^2+n-2}{2}$.

Example 3 We take again the fuzzy measure μ of Example 1, with $u(x) = (3, 1, 6)$. Indeed, we see by Example 2 that μ is 2-additive. Therefore, Equation (5) can be applied, and it gives (see Example 2 for the values of interaction):

$$\begin{aligned} C_\mu(u(x)) &= 0.1(3 \wedge 1) + 0 + 0.1(1 \wedge 6) \\ &\quad + 3 \left(0.25 - \frac{0.1}{2} \right) + 1 \left(0.3 - \frac{0.2}{2} \right) \\ &\quad + 6 \left(0.45 - \frac{0.1}{2} \right) = 3.4 \end{aligned}$$

We observe that, as expected, the result is the same as our computation in Example 1.

ORDINAL MODELS

So far, it was assumed that utility functions were real-valued functions. In many cases, however, scores are given on a finite ordinal scale, such as $\{bad, medium, good\}$. As the fuzzy measure is interpreted as an overall score on binary alternatives, it follows that the fuzzy measure too is defined on the same ordinal scale. However, the arithmetic operations used in the Choquet integral cannot be used on an ordinal scale, and another kind of

integral has to be used, involving in its definition only minimum and maximum, which are the only operations being meaningful on an ordinal scale.

Let us denote the finite ordinal scale by L , with 0 and 1 the lower and upper bounds of L , respectively. Imposing that the overall score be 0 (respectively, 1), if all scores on criteria are 0 (respectively, 1), it can be shown [15] that the only possible aggregation function using only minimum and maximum is the *Sugeno integral* [5], defined by

$$S_\mu(a_1, \dots, a_n) = \bigvee_{i=1}^n (a_i \wedge \mu(\{i, \dots, n\})),$$

where $(a_1, \dots, a_n)$ is the vector of scores, and criteria have been reordered so that $a_1 \leq \dots \leq a_n$, as for the Choquet integral. To be meaningful, the fuzzy measure and all utility functions must take values in L , with $\mu(N) = 1$.

The Sugeno integral keeps many of the properties of the Choquet integral:

1. $S_\mu(u(\mathbf{1}_A, \mathbf{0}_{-A})) = \mu(A)$, for all $A \subseteq N$;
2. $S_\mu(\alpha \wedge u(x)) = \alpha \wedge S_\mu(u(x))$, $S_\mu(\alpha \vee u(x)) = \alpha \vee S_\mu(u(x))$;
3. $u_i(x_i) \leq u_i(x'_i)$ for $i = 1, \dots, n$ implies $S_\mu(u(x)) \leq S_\mu(u(x'))$;
4. $\min_{i=1}^n u_i(x_i) \leq S_\mu(u(x)) \leq \max_{i=1}^n u_i(x_i)$.

However, an important drawback of the Sugeno integral is that it can happen that two alternatives x, x' have the same overall evaluation although $u_i(x_i) > u_i(x'_i)$ for all $i \in N$ (Example 4).

Example 4 Let us consider the scale $L = \{0, 1, \dots, 10\}$ and use the fuzzy measure of Example 1 multiplied by 10, together with $u(x) = (3, 1, 6)$. We obtain:

$$S_\mu(u(x)) = (1 \wedge 10) \vee (3 \wedge 6) \vee (6 \wedge 4) = 4.$$

Note that this is relatively close to 3.4 found in Example 1 with the Choquet integral. Now consider $u(x') = (2, 0, 5)$. We find

$$S_\mu(u(x')) = (0 \wedge 10) \vee (2 \wedge 6) \vee (5 \wedge 4) = 4,$$

that is, $S_\mu(u(x)) = S_\mu(u(x'))$, although x has better scores than x' on each criterion.

IDENTIFICATION OF THE MODEL

Once the utility functions have been determined, the identification of the model amounts to the identification of the fuzzy measure, which, most of the time, will be the solution of an optimization problem under constraints. We give here two main types of optimization problem (we refer the reader to [16] and [4, Chapter 11] for a survey and more detail):

1. *Minimizing the total squared error:* Denoting by $\mathcal{O}$ the set of available alternatives, the data set consists of the vectors $u(x)$ of scores on criteria together with the overall score $y(x)$, for all $x \in \mathcal{O}$. The aim is to minimize the distance to the desired overall scores:

$$\min_{\mu} \sum_{x \in \mathcal{O}} (\mathcal{C}_\mu(u(x)) - y(x))^2.$$

The constraints of the problem are the monotonicity constraints of the fuzzy measure:

$$\mu(A \cup i) - \mu(A) \geq 0, \quad \forall i \in N, \forall A \subseteq N \setminus i,$$

and possibly some information on the Shapley value and interaction indices, such as a partial order or the sign of some interaction index.

2. *Maximum separation of alternatives:* The data consists of a preference relation $\succeq$ on a set $\mathcal{O}$ of alternatives. The objective is to maximize the distance between the overall scores obtained for these alternatives, provided they are compatible with the preference relation (constraints):

$$\begin{aligned} \max \quad & \epsilon \\ \text{subject to} \quad & \mathcal{C}_\mu(u(x)) - \mathcal{C}_\mu(u(x')) \geq \delta + \epsilon, \\ & \forall x, x' \in \mathcal{O}, \text{ such that } x \succeq x' \\ & \mu(A \cup i) - \mu(A) \geq 0, \\ & \forall i \in N, \forall A \subseteq N \setminus i, \end{aligned}$$

where δ is a fixed threshold. As above, additional constraints can be given, pertaining to the Shapley value and interaction indices. It should be noted that contrarily to the first case, this optimization problem may have no solution.

The above optimization problems concern solely the Choquet integral, and are either quadratic (in the first case) or linear (in the second case) programs. For the first case, standard quadratic programming methods can be avoided, and a faster (although suboptimal) heuristic algorithm (HLMS, heuristic least mean squares) can be used instead [17, 18]. For the Sugeno integral, only heuristic methods such as genetic algorithms can be used [19].

GAME-THEORETIC METHODS IN COUNTERTERRORISM AND SECURITY

VICKI M. BIER

Department of Industrial and Systems
Engineering, University of
Wisconsin-Madison, Madison,
Wisconsin

After the September 11, 2001, terrorist attacks on the World Trade Center and the Pentagon, and the subsequent anthrax attacks in the United States, there has been an increased interest in security. However, security problems pose some significant challenges to conventional methods for risk analysis [1,2]. One critical challenge is the intentional nature of terrorist attacks [3].

Protecting against intentional attacks is fundamentally different from protecting against accidents or acts of nature. In particular, an adversary may adopt a different offensive strategy in response to observed security measures, in order to circumvent or disable those measures. For example, Ravid [4] argues that since the adversary can change targets in response to defensive investments, “investment in defensive measures, unlike investment in safety measures, saves a lower number of lives (or other sort of damages) than the apparent direct contribution of those measures.” Game theory [5] provides a way of taking this into account. In particular, game theory identifies the optimal defense against and optimal attack. While it may not be possible to actually predict terrorist attacks, protecting against an optimal attack can arguably be described as conservative. This article discusses approaches for applying game theory to the problem of defending against intentional attacks.

APPLICATIONS OF GAME THEORY TO SECURITY

Game theory has a long history of being applied to security, beginning with military

applications [6–10]. It has also been extensively used in political science [11–13]; for example, in the context of arms control. Recently, game theory has also been applied to computer security [14,15]. Many applications of game theory to security have been by economists [16–27]. Much of this work has been designed to provide *policy insights* [25]—for example, on the relative merits of public versus private funding of defensive investments [23], or deterrence versus defense [19,20,22,27]. Since the events of September 11, however, there has been increased interest in using game theory not only to explore the effects of different policies, but to generate detailed guidance in support of operational-level decisions as well—for example, which assets to protect, or how much to charge for terrorism insurance.

For example, Enders and Sandler [18] and Hausken [21] study substitution effects in security. Enders and Sandler observe that “installation of screening devices in US airports in January 1973 made skyjackings more difficult, thus encouraging terrorists to substitute into other kinds of hostage missions.” Similarly, they note: “If ... the government were to secure its embassies or military bases, then attacks against such facilities would become more costly on a per-unit basis. If, moreover, the government were not at the same time to increase the security for embassy and military personnel when outside their facilities, then attacks directed at these individuals (e.g., assassinations) would become relatively cheaper” (and hence presumably more frequent).

Clearly, security improvements that appear to be justified without taking into account the fact that attacks may be deflected to other targets may turn out to be wasteful (at least from a public perspective) if they merely deflect attacks to other targets of comparable value. Therefore, the Brookings Institution [28] has recommended that “policy-makers should focus primarily on those targets at which an attack would involve a large number of casualties, would

entail significant economic costs, or would critically damage sites of high national significance.”

The Brookings recommendation constitutes a reasonable *zero-order* suggestion about how to prioritize targets for investment. However, it is important to go beyond the zero-order heuristic of protecting only the most valuable or potentially damaging targets, to account for the success probabilities of different attacks, since terrorists appear to take the probability of success into account in their choice of targets. For example, Woo [29] has observed that “Al-Qaeda is . . . sensitive to target hardening,” and that “Osama bin Laden has expected very high levels of reliability for martyrdom operations.” Thus, even if a successful attack against a given target would be highly damaging, that target may not merit as much defensive investment as a target that is less valuable but more vulnerable (and hence more attractive to attackers). Early models that take the success probabilities of potential attacks into account include Woo [29], Bier *et al.* [30], and Major [31].

Both the Brookings recommendations [28] and the results in Bier *et al.* [30] still represent “weakest-link” models, in which defensive investment is allocated only to the target(s) that would cause the most damage if attacked. However, such weakest-link models can be unrealistic in practice. For example, Arce and Sandler [16] note that weakest-link solutions “are not commonly observed among the global and transnational collective action problems confronting humankind.” In particular, real-world decision makers typically *hedge* by defending additional targets, to cover contingencies such as misestimating which targets are most attractive to attackers.

The models in Woo [29] and Major [31] achieve the more realistic result of defensive hedging at optimality, but do so with a restrictive (and possibly questionable) assumption. In particular, these models assume that the attacker can observe “the marginal effectiveness of defense . . . at [each] target” [31], but not which defenses have been implemented. More recent work

[32–34] attempts to achieve the result of defensive hedging at equilibrium in a different manner—assuming (perhaps conservatively) that attackers can observe defensive investments perfectly, but that defenders are uncertain about the attractiveness of possible targets to the attackers. Interestingly, hedging does not always occur in this model. In particular, the results suggest that it is often optimal for the defender to put no investment at all into some targets—especially when the defender is highly resource constrained, and the various potential targets differ greatly in their values (both of which are likely to be the case in practice).

Recently, researchers have begun to focus on allocation of defensive resources in the face of threats from both terrorism and natural disasters [35–38]. In addition, some researchers have begun formally taking into account the effect of deterrence or retaliation on terrorist recruitment [24,39].

Security as a Game between Defenders

The work discussed above views security primarily as a game between attacker and defender. However, defensive strategies adopted by one agent can also affect the incentives faced by other defenders. Some types of defensive actions (such as installation of visible burglar alarms or car alarms) may increase risk to other potential victims (a negative externality), leading to overinvestment in security. Conversely, other types of defensive actions—such as vaccination, fire protection, or use of antivirus protection software—decrease the risk to other potential victims (a positive externality). This type of situation can result in underinvestment in security, and *free riding* by defenders [21,25].

In order to better account for security investments with positive externalities, Kunreuther and Heal [40] propose a model of interdependent security (IDS) where agents are vulnerable to *infection* from other agents; Heal and Kunreuther [41] apply this model to the case of airline security. More specifically, this body of work assumes that the consequences of even a single successful

attack would be catastrophic—leading, for example, to business failure. Under this assumption, Kunreuther and Heal show that failure of one agent to invest in security can make it unprofitable for other agents to invest, even when they would otherwise do so. Moreover, this game can have multiple equilibrium solutions (e.g., one in which all defenders invest in security, and another in which none invest), so coordinating mechanisms can help to ensure that the socially optimal level of investment is reached.

Recent work [42] has extended these results to attacks occurring over time (rather than a *snapshot* model). In this case, differences in discount rates among agents can lead some agents with low discount rates not to invest in security, if other agents (e.g., those with high discount rates) choose not to invest. Thus, heterogeneous time preferences can complicate the task of achieving security.

Unlike the above work, Keohane and Zeckhauser [22] consider both positive and negative externalities among defenders. In particular, they note that reduction of population in a major city (e.g., due to relocation decisions by members of the public) may make all targets in that city less attractive to terrorists, while government investment to make a location safer will tend to attract increased population, making that location more attractive to potential attackers.

COMBINING RISK ANALYSIS AND GAME THEORY

Conventional risk analysis does not explicitly model the adaptive response of potential attackers, and hence may overstate the effectiveness and cost-effectiveness of defensive investments. However, much game-theoretic security work focuses on nonprobabilistic games. Even those models that explicitly consider the success probabilities of potential attacks [29–34,38,40–42] generally treat individual assets in isolation, and fail to consider their possible role as components of a larger system. Therefore,

combining risk analysis with game theory could be fruitful in studying intentional threats to complex systems such as critical infrastructure.

Hausken [43] has integrated probabilistic risk analysis and game theory (although not in the security context), by interpreting system reliability as a public good, and considering the incentives of players responsible for maintaining particular components of a larger system. In particular, by viewing reliability as a game between defenders responsible for different portions of the system, he identifies relationships between the series or parallel structure of the system being analyzed and classic games such as the coordination game, battle of the sexes, chicken, and prisoner's dilemma.

Rowe [44] argues that the implications of “the human variable” in terrorism risk have yet to be adequately appreciated, and presents a framework for evaluating possible defenses in light of terrorists’ ability to “learn from experience and alter their tactics.” This approach has been used in practice to help prioritize defensive investments among multiple potential targets and threat types. Similarly, Paté-Cornell and Guikema [45] discuss the need for “periodic updating of the model and its input” to account for the dynamic nature of terrorism, but do not formally use game theory.

Banks and Anderson [46] apply similar ideas to the threat of intentionally introduced smallpox. Their approach embeds risk analysis in a game-theoretic formulation of the defender’s decision, accounting for both the adaptive nature of terrorism, and also uncertainty about the costs and benefits of particular defenses. They conclude that this approach “captures facets of the problem that are not amenable to either game theory or risk analysis on their own.”

Bier *et al.* [30] use game theory to study security of simple series and parallel systems, as a building block to more complex systems. Results suggest that defending series systems against intentional attack is extremely difficult, if the attacker knows about the system’s defenses. In particular, the attacker’s

ability to respond to the defender's investments deprives the defender of the ability to allocate defensive investments according to their cost-effectiveness; instead, defensive investments in series systems must equalize the strength of all defended components, consistent with results in Dresher [8]. Recent work [47] begins to extend these types of models to more complicated system structures (including both parallel and series subsystems).

Recently, controversy has developed over the use of game theory in homeland security, with some arguing [48] that the assumptions of game theory are unrealistic, and that probabilistic risk analysis provides an adequate means of assessing security threats, and others arguing [49] that game-theoretic insights or other new approaches that explicitly account for adversary objectives are crucial to protection against intelligent adversaries. While both methods have strengths and weaknesses, of course, it seems likely that any good method for assessing security threats will involve some method for explicitly incorporating adversary objectives, even if not in a formally game-theoretic manner.

CONCLUSIONS

As noted above, protecting complex systems against intentional attacks is likely to require a combination of game theory and risk analysis. Risk analysis by itself does not account for the attacker's responses to security measures, while game theory often deals with individual assets in isolation, rather than with complex networked systems (such as computer systems, electrical transmission systems, or transportation systems). Approaches that combine risk models and game methods can take advantage of the strengths of both approaches.

GENERATING HOMOGENEOUS POISSON PROCESSES

RAGHU PASUPATHY
Department of Industrial and Systems
Engineering, Virginia Tech,
Blacksburg, Virginia

Recall that a *counting process* $\{N_t, t \geq 0\}$ is a stochastic process defined on a sample space Ω such that for each $\omega \in \Omega$, the function $N_t(\omega)$ is a “realization” of the number of “events” happening in the interval $(0, t]$, with $N_0(\omega) = 0$. By this definition, $N_t(\omega)$ is automatically integer valued, nondecreasing, and right-continuous for each ω . A nonhomogeneous Poisson process is a type of counting process that is characterized as follows.

Definition 1. A counting process $\{N_t, t \geq 0\}$ is called a nonhomogeneous Poisson process if:

- (i) $\forall t, s \geq 0$, and $0 \leq u \leq t$, $N_{t+s} - N_t$ is independent of N_u ;
- (ii) $\forall t, s \geq 0$, $\Pr\{N_{t+s} - N_t \geq 2\} = o(s)$; and
- (iii) $\forall t, s \geq 0$, $\Pr\{N_{t+s} - N_t = 1\} = \lambda(t)s + o(s)$, where $\lambda(t)$ is some positive-valued function.

Definition 1 has been adopted from Billingsley [1, p. 297], with the notation $o(s)$ used in the usual sense—to denote a function $v(s)$ that satisfies $\lim_{s \rightarrow 0} v(s)/s = 0$ [2, p. 1]. The function $\lambda(t)$ appearing in Definition 1, called the *rate function*, completely characterizes the Poisson process. Various other definitions of a Poisson process are available and quite prevalent. See, for instance, Cox and Lewis [3], Ross [4], Gnedenko and Kovalenko [5], and Çinlar [6] (Section 23 in Ref. 1 discusses the equivalence of various definitions of the Poisson process.) For example, Çinlar [6] provides the following definition based on the sample-paths of N_t that is particularly relevant to the current context.

Definition 2. A counting process $\{N_t, t \geq 0\}$ is called a nonhomogeneous Poisson process if:

- (i) $\forall t, s \geq 0$, and $0 \leq u \leq t$, $N_{t+s} - N_t$ is independent of N_u ;
- (ii) $\forall t \geq 0$ and for almost all ω , the mapping $t \rightarrow N_t(\omega)$ has jumps of unit magnitude only, that is, $N_t(\omega) - \lim_{s \uparrow t} N_s(\omega) = 0$ or $1 \forall t \geq 0$ and for almost all ω .

It is worth noting that Definitions 1 and 2 are not equivalent—the latter definition allows (unit) jumps of positive probability in the sample-paths, in which case, the rate function $\lambda(t)$ appearing in Definition 1 simply does not exist.

In what follows, we discuss existing methods to generate pseudorandom numbers from a nonhomogeneous Poisson process. By this, we mean generating, on a digital computer, a realization of event times $\{t_i, i = 1, 2, \dots\}$ from a Poisson process. The Poisson process is specified either through its rate function $\lambda(t)$ (when it exists), or more generally through its expectation function $\Lambda(t) \equiv E[N_t]$. When the rate function $\lambda(t)$ exists, $\Lambda(t) = \int_0^t \lambda(y) dy$.

GENERATING NONHOMOGENEOUS POISSON PROCESSES

As discussed in (see **Generating Nonhomogeneous Poisson Processes**) homogeneous Poisson processes can be generated very efficiently and in a fairly straightforward fashion. This is in some contrast with nonhomogeneous Poisson processes, where generation methods tend to be much less straightforward. We categorize the available methods for generating nonhomogeneous Poisson processes into three broad groups: (i) inversion methods, (ii) order statistics methods, and (iii) acceptance–rejection methods. We discuss each of these in what follows.

Inversion

The earliest known inversion method seems to be the technique devised by Çinlar [6, p. 96]. It is based on an interesting property of nonhomogeneous Poisson processes with a continuous expectation function $\Lambda(t)$.

Theorem 1 [Çinlar, 1975]. *Let $\Lambda(t), t \geq 0$ be a positive-valued, continuous, nondecreasing function. Then the random variables $T_1, T_2, \dots$ are event times corresponding to a nonhomogeneous Poisson process with expectation function $\Lambda(t)$ if and only if $\Lambda(T_1), \Lambda(T_2), \dots$ are the event times corresponding to a homogeneous Poisson process with rate one.*

Theorem 1 provides a method to generate event times from a nonhomogeneous Poisson process that is straightforward in principle. First, generate event times from a homogeneous Poisson process with rate one, and then invert $\Lambda(\cdot)$ to obtain the event times of the required process.

Algorithm 1 (Çinlar's Method).

- (0) Initialize $s = 0$.
- (1) Generate $u \sim U(0, 1)$.
- (2) Set $s \leftarrow s - \log(u)$.
- (3) Set $t \leftarrow \inf\{v : \Lambda(v) \geq s\}$.
- (4) Deliver t .
- (5) Go to Step (1).

When the expectation function $\Lambda(t)$ falls in a particular family of functions that facilitates efficient analytic inversion in Step (3), Algorithm 1 tends to be very fast. This happens only infrequently, however, and implementation often involves employing expensive numerical quadrature for inversion [7] in Step (3). Adoption of Çinlar's method should thus be considered accordingly. Code for a rudimentary version of Çinlar's method can be found through the website <https://filebox.vt.edu/users/pasupath/pasupath.htm>.

Theorem 1 assumes the continuity of the expectation function $\Lambda(t)$. When $\Lambda(t)$ has discontinuities, Algorithm 1 can be adapted in

a somewhat straightforward fashion. See, Çinlar [6, p. 100] and Resnick [8] for different treatments.

Another inversion approach to generating nonhomogeneous Poisson processes stems from the distribution of inter-event times. Specifically, consider the i th inter-event time $X_i = T_{i+1} - T_i$ conditional on the first i event times $T_1 = t_1, T_2 = t_2, \dots, T_i = t_i$. We can derive the cdf of X_i (conditional on $T_1, T_2, \dots, T_i$) as follows.

$$\begin{aligned}
 F_{t_i}(x) &= \Pr\{X_i \leq x | T_j = t_j, j = 1, 2, \dots, i\} \\
 &= \Pr\{N_{t_i+x} - N_{t_i} \geq 1 | T_j = t_j, \\
 &\quad j = 1, 2, \dots, i\} \\
 &= \Pr\{N_{t_i+x} - N_{t_i} \geq 1\} \\
 &= 1 - \Pr\{N_{t_i+x} - N_{t_i} = 0\} \\
 &= 1 - \exp(-\Lambda(t_i + x) + \Lambda(t_i)), \quad (1)
 \end{aligned}$$

where the third equality is from the independent increments property of the Poisson process. (We again note here that Equation (1) is not true in general if $\Lambda(t)$ has jumps. It can, however, be shown that Equation (1) will still hold if the location of the jumps has a Poisson number of events with mean equal to the value of the jump [8].)

The cdf appearing in Equation (1) provides a natural method of generating a nonhomogeneous Poisson process—given the previous i event times, generate the $(i+1)$ th event time as the sum of the i th event time and the i th inter-event time distributed according to F_{t_i} .

Algorithm 2.

- (0) Initialize $t = 0$.
- (1) Generate $x \sim F_t$ given by Equation (1).
- (2) Set $t \leftarrow t + x$.
- (3) Deliver t .
- (4) Go to Step (1).

Like Çinlar's method, Algorithm 2 is direct, exact, and elegant. However, and again like Çinlar's method, Algorithm 2 is efficient only when the form of the expectation function $\Lambda(t)$ renders easy generation from

F_t . Specifically, suppose the cdf-inverse method is used to generate from F_t in Step (1). If the nonhomogeneous Poisson process is specified through the rate function $\lambda(t)$, this amounts to finding x satisfying

$$\int_t^{t+x} \lambda(y) dy = -\ln(1-u), \text{ where } u \sim U(0,1). \quad (2)$$

In general, the problem appearing in Equation (2) can be solved only using numerical quadrature [7], and can hence be computationally expensive. (Public domain software is available for this purpose [9].)

By contrast, if enough structure is present and known, efficient tailor-made techniques can be devised to solve Equation (2). One such example is the piecewise-linear rate function considered by Klein and Roberts [10], and by Lee *et al.* [11], with success. Specifically, Klein and Roberts [10] assume that $\lambda(t)$ is a continuous, piecewise-linear function connecting the points $(0, \lambda_0), (t_1, \lambda_1), (t_2, \lambda_2), \dots$. Therefore, generating from the distribution F_t in Step (1) of Algorithm 2 amounts to identifying x such that $-\log(1-u) = \Lambda(t_i, x)$ where $\Lambda(t_i, x) \equiv \Lambda(t_i + x) - \Lambda(t_i)$. Through straightforward integration of the piecewise-linear function, Klein and Roberts [10] come up with an expression for the function $\Lambda(t_i, x)$ and the corresponding root x that satisfies $-\log(1-u) = \Lambda(t_i, x)$.

One important point needs to be noted in implementing the inversion methods that we have discussed. Depending on the nature of the expectation function $\Lambda(t)$, the distribution of the time until the next event may not be well defined. In particular, there may be a positive probability of observing no events past a particular point in time, that is, there exists $\delta > 0$ such that $\Pr\{X_i > x\} > \delta$ for all $x > 0$. In such a case, Step (3) in Çinlar's method may have no solution, and F_t in Equation (1) may not be a proper cdf.

Order Statistics

Let us now state a general result on the distribution of the event times of a nonhomogeneous Poisson process with expectation function $\Lambda(t)$.

Theorem 2 [Cox and Lewis, 1962]. *Let $T_1, T_2, \dots$ be random variables representing the event times of a nonhomogeneous Poisson process with continuous expectation function $\Lambda(t)$, and let N_t represent the total number of events occurring before time t in the process. Then, conditional on the number of events $N_{t_0} = n$, the event times $T_1, T_2, \dots, T_n$ are distributed as order statistics from a sample with distribution function $F(t) = \Lambda(t)/\Lambda(t_0)$ for $t \in [0, t_0]$.*

Theorem 2 is a generalization of the result for homogeneous Poisson processes. It naturally gives rise to Algorithm 3 for generating random variates from a nonhomogeneous Poisson process with expectation function $\Lambda(t)$ in a fixed interval $[0, t_0]$.

Algorithm 3.

- (1) Generate $n \sim \text{Poisson}(\Lambda(t_0))$.
- (2) Independently generate n random variates $t'_1, t'_2, \dots, t'_n$ from the cdf $F(t) = \Lambda(t)/\Lambda(t_0)$.
- (3) Order $t'_1, t'_2, \dots, t'_n$ to obtain $t_1 = t'_{(1)}, t_2 = t'_{(2)}, \dots, t_n = t'_{(n)}$.
- (4) Deliver $t_1, t_2, \dots, t_n$.

The efficiency of Algorithm 3 depends critically on Step (2), where n random variates are to be generated from the cdf $F(t)$. If $\lambda(t)$ is assumed to be log-linear ($\lambda(t) = \lambda e^{\alpha_1 t}$) as in Ref. 12, Algorithm 3 becomes very efficient since $F(t) = (e^{\alpha_1 t} - 1)/(e^{\alpha_1 t_0} - 1), t \in [0, t_0], \alpha_1 \neq 0$ is easily invertible. Lewis and Shedler, in the same article [12], provide an even faster variant based on gap statistics. This is extended to the case of second degree exponential polynomial rate functions (i.e., $\lambda(t) = \exp(\alpha_0 + \alpha_1 t + \alpha_2 t^2)$) in Ref. 13.

Acceptance-Rejection

Currently the most popular method for generating nonhomogeneous Poisson processes is the “process analogue” of acceptance-rejection called *thinning* [14]. The intuitive idea behind thinning is to first find a constant rate function $\lambda_u(t) = \lambda_u$, which dominates the desired rate function $\lambda(t)$, next generate from

the implied homogeneous Poisson process with rate $\lambda_u(t) = \lambda_u$, and then reject an appropriate fraction of the generated events so that the desired rate $\lambda(t)$ is achieved. The following theorem is the basis for this procedure.

Theorem 3 [Lewis and Shedler, 1979]. *Consider a nonhomogeneous Poisson process with rate function $\lambda_u(t), t \geq 0$. Suppose that $T_1^*, T_2^*, \dots, T_n^*$ are random variables representing event times from the nonhomogeneous Poisson process with rate function $\lambda_u(t)$, and lying in the fixed interval $(0, t_0]$. Let $\lambda(t)$ be a rate function such that $0 \leq \lambda(t) \leq \lambda_u(t)$ for all $t \in [0, t_0]$. If the i th event time T_i^* is independently deleted with probability $1 - \lambda(t)/\lambda_u(t)$ for $i = 1, 2, \dots, n$, then the remaining event times form a nonhomogeneous Poisson process with rate function $\lambda(t)$ in the interval $(0, t_0]$.*

A thinning algorithm for generating random variates from a nonhomogeneous Poisson process follows immediately.

Algorithm 4.

- (0) Initialize $t = 0$.
- (1) Generate $u_1 \sim U(0, 1)$.
- (2) Set $t \leftarrow t - \frac{1}{\lambda_u} \log u_1$.
- (3) Generate $u_2 \sim U(0, 1)$ independent of u_1 .
- (4) If $u_2 \leq \lambda(t)/\lambda_u$ then deliver t .
- (5) Go to Step (1).

In the above thinning algorithm, at any time t , a variate generated from the majorizing rate function $\lambda_u(t) = \lambda_u$ is accepted with probability $\lambda(t)/\lambda_u$. The efficiency thus depends critically on how “snugly” λ_u approximates $\lambda(t)$ —rate functions $\lambda(t)$ that exhibit heavy fluctuations in time will render the thinning algorithm inefficient. A proof that the thinning algorithm in fact produces the desired stochastic process can be found in Ref. 14.

Ross [15] provides a straightforward modification to the thinning method with the objective of mitigating excessive rejection (Also see Ref. 16, p. 179.) The intuitive idea behind this extension is *piecewise*

thinning—majorize the desired rate function using an appropriately chosen piecewise constant function having k pieces, and then perform regular thinning within each piece. Specifically, first divide the horizon of interest $[0, t_0]$ into k intervals $[s_{j-1}, s_j], j = 1, 2, \dots, k$, and choose constants λ_j satisfying $\lambda_j \geq \sup_{t \in [s_{j-1}, s_j]} \{\lambda(t)\}$. Random variates from a homogeneous Poisson process are then generated in the interval $[s_{j-1}, s_j], j = 1, 2, \dots, k$, by generating exponential random variates with mean $1/\lambda_j, j = 1, 2, \dots, k$. The resulting event times are each accepted independently with probability $\lambda(t)/\lambda_j, j = 1, 2, \dots, k$. Certain simple edge corrections are required when a generated exponential inter-event time straddles two pieces of the majorizing function. A complete algorithm listing can be found in Ref. 15 (p. 85).

While piecewise thinning alleviates excessive rejection, it can still be inefficient depending on how well the majorizing step function approximates the rate function. Modern methods, thus, go one step further than piecewise thinning and construct a majorizing function $\lambda_u(t)$ that is both a good approximation of the rate function and has a form that lends itself to easy generation. This results in a method that is a hybrid of two methods—usually an inversion method such as Algorithm 2 used to generate random variates from the constructed majorizing function $\lambda_u(t)$, and a thinning method to reject a correct fraction of the generated random variates. We now state this in the form of an algorithm.

Algorithm 5.

- (0) Initialize $t = 0$.
- (1) Generate $x \sim F_t$ where $F_t(x)$ is given in Equation (1) with $\Lambda(t) = \int_0^t \lambda_u(t) dt$.
- (2) Set $t \leftarrow t + x$.
- (3) Generate $u \sim U(0, 1)$ independent of x .
- (4) If $u \leq \lambda(t+x)/\lambda_u(t+x)$ then deliver t .
- (5) Go to Step (1).

Such a hybrid algorithm has been used with much success to generate a nonhomogeneous Poisson process on a fixed interval $[0, t_0]$ in

Ref. 11. The majorizing function $\lambda_u(t)$ used in Ref. 11 is a continuous piecewise-linear function that is optimal in a certain precise sense.

GENERATING TWO-DIMENSIONAL POISSON PROCESSES

A counting process $\{N(t), t \geq 0\}$ is said to constitute a two-dimensional nonhomogeneous Poisson process on $C \subseteq \mathbb{R}^2$ with rate function $\lambda(x, y) > 0$ if

- (i) The number of events in a region $R \subseteq C$ is Poisson distributed with parameter $\Lambda(R) = \iint_R \lambda(x, y) dx dy$.
- (ii) The number of events occurring in any finite set of nonoverlapping regions are mutually independent.

(We do not go into details about the complete characterization of the nature of C or the subsets R , for which (1) and (2) should be satisfied. See Ref. 8 (p. 303) for a more rigorous treatment.) The Poisson process is said to be a homogeneous Poisson process if $\lambda(x, y)$ in the above definition is constant on C , that is, $\lambda(x, y) = \lambda$ for $(x, y) \in C$ [17]. For generation from a two-dimensional homogeneous Poisson process, consult the section titled “Generation of Homogeneous Poisson Processes.”

For generating nonhomogeneous Poisson processes in a bounded region C , a simple first algorithm is based on the idea that the location (X, Y) of an event in C , conditional on the number of events $N = n$ that occur in C , is distributed over the region C according to the probability density function

$$f(x, y) = \frac{\lambda(x, y)}{\iint_C \lambda(x, y) dx dy}, \quad (x, y) \in C. \quad (3)$$

(See Chapter 4 of Ref. 8 for more on this. Particularly, the above idea extends seamlessly even into higher dimensions.) This, combined with the fact that the number of events N in C is Poisson distributed with mean $\iint_C \lambda(x, y) dx dy$, gives rise to a conceptually simple algorithm for generating events.

Algorithm 6.

- (1) Generate $n \sim \text{Poisson}(\iint_C \lambda(x, y) dx dy)$.
- (2) If $n = 0$ then exit. Otherwise independently generate n events $(x_i, y_i), i = 1, 2, \dots, n$ that are distributed in C according to the density $f(x, y)$ given in Equation (3).
- (3) Deliver $(x_i, y_i), i = 1, 2, \dots, n$.

Of course, the ease with which the above algorithm is implemented will depend on the nature of the rate function $\lambda(x, y)$. Particularly, it will depend on how easily $\lambda(x, y)$ is integrated over C , and whether $f(x, y)$ lends itself to easy generation. A lot is known about generation from continuous densities with arbitrary form—see Ref. 18 for more on this.

Another popular method for generating nonhomogeneous Poisson processes is the multidimensional analogue of thinning, and stems from a theorem by Lewis and Shedler [14].

Theorem 4 [Lewis and Shedler, 1979]. *Let $(X_i, Y_i), i = 1, 2, \dots$ be the Cartesian coordinates of a two-dimensional Poisson process on $C \subseteq \mathbb{R}^2$ with rate function $\lambda^*(x, y) \geq 0$. If the i th event is independently deleted with probability $1 - \lambda(x, y)/\lambda^*(x, y)$ where $0 \leq \lambda(x, y) \leq \lambda^*(x, y)$ for all $(x, y) \in C$, the resulting process is a Poisson process on C with rate function $\lambda(x, y)$.*

A basic thinning algorithm would thus involve identifying λ_u such that $\lambda_u \geq \lambda(x, y)$ for all $(x, y) \in C$, generating random variates from a homogeneous Poisson process with rate λ_u (see the section titled “Generation of Homogeneous Poisson Processes”), and then deleting events with probability $1 - \lambda(x, y)/\lambda_u$. As in one-dimensional thinning, such an algorithm would be very inefficient in contexts where the rate function $\lambda(x, y)$ exhibits major fluctuations. Methods that are analogous to piecewise thinning and the hybrid method for one-dimensional thinning, if devised, will potentially prove much more efficient.

A more recent idea for generating nonhomogeneous Poisson processes is provided

by Saltzman *et al.* [19], and is based on the idea of conditioning. (See also Section 4.10 of Ref. 8 for a deeper treatment of this idea.) Specifically, they note the following two facts about a two-dimensional nonhomogeneous Poisson process with rate function $\lambda(x, y) > 0$ on $C \subset \mathbb{R}^2$.

- (i) If $\{(X_i, Y_i)\}$ are events corresponding to the two-dimensional process, then the abscissae $\{X_i\}$ correspond to a one-dimensional nonhomogeneous Poisson process with rate function $\lambda_X(x) = \int_{C(x)} \lambda(x, y) dy$, where $C(x) = \{y : (x, y) \in C\}$.
- (ii) If (X, Y) denotes the location of an event from the two-dimensional process, the conditional random variable $Y|X = x$ has the probability density function $\lambda(x, y)/\lambda_X(x)$.

The above two facts give rise to a generation algorithm that first generates the abscissa of an event and then generates its ordinate through the conditional density function provided in (2). Like Algorithm 6, the efficiency of the resulting algorithm depends on the tractability of the rate functions $\lambda(x, y)$ and $\lambda_X(x)$. We summarize this as Algorithm 7 below.

Algorithm 7.

- (1) Initialize $i = 0$.
- (2) Generate x_i according to the one-dimensional nonhomogeneous Poisson process with rate function $\lambda_X(x)$.
- (3) Generate y_i according to the probability density function $\lambda(x_i, y)/\lambda_X(x_i)$.
- (4) Deliver (x_i, y_i) .
- (5) Set $i = i + 1$ and go to Step (2).

GENERATING NONHOMOGENEOUS POISSON PROCESSES

RAGHU PASUPATHY

Department of Industrial and
Systems Engineering,
Virginia Tech, Blacksburg,
Virginia

Recall that a *counting process* $\{N_t, t \geq 0\}$ is a stochastic process defined on a sample space Ω such that for each $\omega \in \Omega$, the function $N_t(\omega)$ is a “realization” of the number of “events” happening in the interval $(0, t]$, with $N_0(\omega) = 0$. By this definition, $N_t(\omega)$ is automatically integer valued, nondecreasing, and right-continuous for each ω . A homogeneous Poisson process is a type of counting process that is characterized as follows:

Definition 1. A counting process $\{N_t, t \geq 0\}$ is called a homogeneous Poisson process if:

- (i) $\forall t, s \geq 0$, and $0 \leq u \leq t$, $N_{t+s} - N_t$ is independent of N_u ;
- (ii) $\forall t, s \geq 0$, $\Pr\{N_{t+s} - N_t \geq 2\} = o(s)$; and
- (iii) $\forall t, s \geq 0$, $\Pr\{N_{t+s} - N_t = 1\} = \lambda s + o(s)$, where $\lambda > 0$.

Definition 1 has been adopted from Ross [1], Chapter 2, with the notation $o(h)$ used in the usual sense—to denote a function $v(h)$ that satisfies $\lim_{h \rightarrow 0} v(h)/h = 0$ [2, p. 1]. The constant $\lambda > 0$ appearing in Definition 1 is called the *rate of the Poisson process*. Stipulation (i) ensures that the resulting process has *independent increments*, that is, the number of events happening in disjoint time intervals is independent. Likewise, the stipulations (ii) and (iii) ensure that the process has *stationary increments*, that is, the distribution of the number of events happening in an interval depends only on the length of the interval. Definition 1 implies that the time between events are independent and identically distributed

(i.i.d.) exponential random variables with mean $1/\lambda$ [1, p. 64]. Moreover, the number of events in any fixed interval of time with length t has a Poisson distribution with mean λt . The latter fact motivates an alternative equivalent definition of a Poisson process.

Definition 2. A counting process $\{N_t, t \geq 0\}$ is called a homogeneous Poisson process if:

- (i) $\forall t, s \geq 0$, and $0 \leq u \leq t$, $N_{t+s} - N_t$ is independent of N_u ; and
- (ii) $\forall t, s \geq 0$, $\Pr\{N_{t+s} - N_t = j\} = \exp\{-\lambda s\} \frac{(\lambda s)^j}{j!}$, $j = 0, 1, \dots$.

That Definitions 1 and 2 are equivalent follows in a rather straightforward manner (see Ref. 1, p. 61 for a proof).

A remarkable, completely qualitative definition of a homogeneous Poisson process is provided by Çinlar [3, p. 71].

Definition 3. A counting process $\{N_t, t \geq 0\}$ is called a homogeneous Poisson process if:

- (i) $\forall t \geq 0$ and almost all ω , the mapping $t \rightarrow N_t(\omega)$ has jumps of unit magnitude only; that is, $N_t(\omega) - \lim_{s \uparrow t} N_s(\omega) = 0$ or $1 \forall t \geq 0$ and for almost all ω ;
- (ii) $\forall t, s \geq 0$, and $0 \leq u \leq t$, $N_{t+s} - N_t$ is independent of N_u ; and
- (iii) $\forall t, s \geq 0$, the distribution of $N_{t+s} - N_t$ does not depend on t .

(Çinlar [3, p. 71] demonstrates that the above assumptions are sufficient to ensure that assumptions (ii) and (iii) of Definition 1 hold.)

In what follows, we discuss existing methods to generate pseudorandom numbers from a homogeneous Poisson process. By this we mean generating, on a digital computer, a realization of event times $\{t_i, i = 1, 2, \dots\}$ from a homogeneous Poisson process that is specified through its rate λ . (For a more general definition of a Poisson process and its generation on a digital computer, see **Generating Homogeneous Poisson Processes**.)

GENERATION ON THE NONNEGATIVE REAL LINE

Generating random variates from a homogeneous Poisson process is straightforward upon noting that the interevent times in such a process are i.i.d. exponential random variables with mean $1/\lambda$. This is owing to the fact that exponential random variates can be generated with ease through the cdf-inverse method [4,5]. Algorithm 1 thus obtains the required Poisson process realization by independently generating exponential random variates and then summing them.

Algorithm 1.

- (0) Initialize $t = 0$.
- (1) Generate $u \sim U(0, 1)$.
- (2) Set $t \leftarrow t - \frac{1}{\lambda} \log(u)$.
- (3) Deliver t .
- (4) Go to Step (1).

(Standard packages use more elaborate techniques that avoid the use of the “log” function in Step (2).) Another straightforward method to generate such realizations arises from a well-known property of a homogeneous Poisson process. Conditioned on the number of events $N(t_0) = n$ that occur in the fixed interval $[0, t_0]$, the event times $T_1, T_2, \dots, T_n$ of a homogeneous Poisson process are distributed as order statistics from a uniform distribution supported on $[0, t_0]$ [6]. (See *Generating Homogeneous Poisson Processes* for a more general result and a proof.) This property gives rise to an algorithm to generate events from a homogeneous Poisson process confined to the fixed interval $[0, t_0]$. We list this as Algorithm 2.

Algorithm 2.

- (1) Generate $n \sim \text{Poisson}(\lambda t)$.
- (2) If $n = 0$ then exit. Otherwise independently generate $u_1 \sim U(0, 1)$, $u_2 \sim U(0, 1)$, $\dots$, $u_n \sim U(0, 1)$, and sort (in increasing order) to obtain $u_{(1)}, u_{(2)}, \dots, u_{(n)}$.
- (3) Set $t_i \leftarrow t_0 u_{(i)}$, $i = 1, 2, \dots, n$.
- (4) Deliver t_i , $i = 1, 2, \dots, n$.

In Step (1), the Poisson random variate n can be generated using any number of available

methods, most notably table-based methods [7–10] and cdf-inverse adaptations [11]. See Ref. 5 for a complete treatment. The sorting operation in Step (2) is $O(n \log n)$ and so the efficiency of Algorithm 2 depends on the magnitudes of t_0 and λ .

GENERATION ON THE PLANE

A counting process $\{N(t), t \geq 0\}$ is said to constitute a two-dimensional homogeneous Poisson process on $C \subseteq \mathbf{R}^2$ with rate $\lambda \geq 0$ if:

- (i) the number of events in a region $R \subseteq C$ is Poisson distributed with parameter $\Lambda(R) = \int_R \lambda \, dV = \lambda A(R)$, where $A(R)$ is the volume of the region R ;
- (ii) the number of events occurring in any finite set of nonoverlapping regions are mutually independent.

(For a more general definition of a Poisson process on a plane, and corresponding generation methods on a digital computer, see *Generating Homogeneous Poisson Processes*.)

Generation from a two-dimensional homogeneous Poisson process with rate λ on a circle of radius $r > 0$ turns out to be easy based on the following result by Lewis and Shedler [12]. (See also Rubinstein and Kroese [13, p. 70].)

Theorem 1. [Lewis and Shedler, 1979]. Suppose $(R_1, \theta_1), (R_2, \theta_2), \dots, (R_N, \theta_N)$ are the polar coordinates of $N > 0$ events from a homogeneous Poisson process on the circle $C \equiv \{(x, y) : x^2 + y^2 \leq r^2\}$. Then, conditional on $N = n$, the ordered event radii $R_{(1)}, R_{(2)}, \dots, R_{(n)}$ are order statistics from the density $f(z) = 2z/r^2$, $z \in [0, r]$. Furthermore, $\theta_1, \theta_2, \dots, \theta_n$ are i.i.d. uniform on $[0, 2\pi]$ and independent of $R_1, R_2, \dots, R_n$.

The resulting algorithm for generating events from a homogeneous Poisson process on a circle of radius r thus involves first generating the number of events $N = n$ from a Poisson distribution with parameter $\pi r^2 \lambda$, then generating the radii $R_{(1)}, R_{(2)}, \dots, R_{(n)}$ as order statistics from the density $f(z)$,

and then finally generating the angles $\theta_1, \theta_2, \dots, \theta_n$ uniformly (and independently) from $[0, 2\pi]$.

Algorithm 3.

- (0) Generate $n \sim \text{Poisson}(\pi r^2 \lambda)$. If $n = 0$ then exit. Otherwise generate $u_1 \sim U(0, 1)$, $u_2 \sim U(0, 1), \dots, u_n \sim U(0, 1)$ independently.
- (1) Set $R_1 \leftarrow r\sqrt{u_1}, R_2 \leftarrow r\sqrt{u_2}, \dots, R_n \leftarrow r\sqrt{u_n}$.
- (2) Sort $R_1, R_2, \dots, R_n$ in ascending order to obtain $R_{(1)}, R_{(2)}, \dots, R_{(n)}$.
- (3) Generate $u_{n+1} \sim U(0, 1)$, $u_{n+2} \sim U(0, 1), \dots, u_{2n} \sim U(0, 1)$ independently.
- (4) Set $\theta_1 \leftarrow 2\pi u_{n+1}, \theta_2 \leftarrow 2\pi u_{n+2}, \dots, \theta_n \leftarrow 2\pi u_{2n}$.
- (5) Deliver $(R_{(1)}, \theta_1), (R_{(2)}, \theta_2), \dots, (R_{(n)}, \theta_n)$.

(In the above algorithm, Step (2) is not required if there is no notion of ordering that is implicit in the abscissa and ordinate.)

Ross [14] gives a method to extend Algorithm 3 to the context of more irregular regions. For instance, suppose we want to generate events from a homogeneous Poisson process in the region bounded by the first quadrant, the positive valued function $f(x)$, and the line $x = T$, that is, the region of interest $C \equiv \{(x, y) : x \geq 0, y \geq 0, y \leq f(x), x \leq T\}$. Ross [14] shows that the order statistics $X_{(1)}, X_{(2)}, \dots, X_{(N)}$ of the x -coordinates of the events are such that $\int_{X_{(i-1)}}^{X_{(i)}} f(x) dx, X_{(0)} = 0, i = 1, 2, \dots$, are i.i.d. exponential with mean $1/\lambda$. The corresponding i th y -coordinate Y_i is uniformly distributed between 0 and $f(X_{(i)})$. This gives rise to an algorithm that is straightforward, at least in principle.

Algorithm 4.

- (0) Initialize $j = 1, n = 0, w = 0, x_0 = 0$.
- (1) Generate $u_j \sim U(0, 1)$ independently.
- (2) Set $w_j \leftarrow -(1/\lambda) \ln(1 - u_j)$.
- (3) Set $w \leftarrow w + w_j$.
- (4) If $w \leq \int_0^T f(x) dx$ then set $n \leftarrow n + 1$ and go to Step (1).
- (5) If $n = 0$ then exit. Otherwise solve for $x_{(i)}, i = 1, 2, \dots, n$ satisfying $\int_{x_{(i-1)}}^{x_{(i)}} f(x) dx = w_i$.
- (6) Generate $u_{n+1} \sim U(0, 1), u_{n+2} \sim U(0, 1), \dots, u_{2n} \sim U(0, 1)$ independently.
- (7) Set $y_i \leftarrow u_{n+if}(x_i)$.
- (8) Deliver $(x_{(i)}, y_i), i = 1, 2, \dots, n$.

The efficiency of Algorithm 4 depends critically on the inversion in Step (5). Theorem 1 can be generalized even further to give a result that is the multidimensional analogue of the order statistics property discussed in the section titled “Generation on the Nonnegative Real Line.” Specifically, consider a two-dimensional homogeneous Poisson process defined on an arbitrary region C . Then it is seen somewhat easily that the location (X, Y) of an event on the plane, conditional on the number of events $N = n$, is uniformly distributed over the region C [15, p. 359]. This then gives rise to a very simple algorithm that is analogous to Algorithm 2, and generalizes Algorithm 3.

Algorithm 5.

- (1) Generate $n \sim \text{Poisson}(\lambda A(C))$.
- (2) If $n = 0$ then exit. Otherwise independently generate n points $(x_i, y_i), i = 1, 2, \dots, n$ that are uniformly distributed in C .
- (3) Deliver $(x_i, y_i), i = 1, 2, \dots, n$.

If the region C is irregular, Step 2 may not be straightforward. In such a case, a two-dimensional homogeneous process can be generated on any convenient region $\bar{C}$ (e.g., a rectangle) that covers C , and the events falling within C can be delivered as a realization of the required process.

STOCHASTIC GRADIENT METHODS

Gradient descent methods (Borkar [1], Guler [2], Spall [3]) are based on the elementary observation that if f is a continuously differentiable function from $\mathbb{R}^d$ to $\mathbb{R}$, then f decreases faster in the opposite direction of its gradient ∇f . More precisely, any solution $\theta(t)$ of the differential equation

$$\frac{\partial \theta}{\partial t} = -\nabla f(\theta) \quad (1)$$

satisfies

$$\frac{\partial f(\theta(t))}{\partial t} = \left\langle \nabla f(\theta(t)), \frac{\partial \theta}{\partial t} \right\rangle = -\|\nabla f(\theta(t))\|^2,$$

which indicates that f is decreasing on the path $\theta(t)$. Suppose that now f is a convex function, then f reaches a minimum at a critical point θ^* such that $\nabla f(\theta^*) = 0$, and $\theta(t)$ converges to θ^* as t tends to infinity. Gradient descent methods have been introduced in order to estimate the critical points θ^* via a discretization of the previous differential equation. They are based on the recursive construction of a sequence (θ_n) satisfying

$$\theta_{n+1} = \theta_n - \gamma_{n+1} \nabla f(\theta_n)$$

where the step size γ_n has to be carefully chosen. In general, the assumptions needed for the convergence of θ_n to θ^* are that the sequence (γ_n) decreases to zero and that

$$\sum_{n=1}^{\infty} \gamma_n = \infty.$$

We can observe that if the above sum converges, then θ_n may not converge to θ^* . From a practical point of view, one can choose

$$\gamma_n = \frac{c}{d+n}$$

with a suitable choice of the positive constants c and d . More details on the practical choice of the sequence (γ_n) may be found in Spall ([3], p. 106). Let us consider the illustrative example of quadratic forms on $\mathbb{R}^d$. Suppose that

$$f(\theta) = \theta' A \theta + \langle b, \theta \rangle$$

where A is a symmetric, positive-definite square matrix of order d and $b \in \mathbb{R}^d$. Then, we clearly have $\nabla f(\theta) = 2A\theta + b$ so that f reaches a minimum at $\theta^* = -A^{-1}b/2$. Then, the gradient descent algorithm can be rewritten as

$$\theta_{n+1} = \theta_n - \gamma_{n+1}(2A\theta_n + b).$$

Then, $\theta_{n+1} - \theta^* = (I - 2A\gamma_{n+1})(\theta_n - \theta^*)$, which implies that θ_n converges to θ^* as soon as the step size $\gamma_n \leq 1/(2\lambda_d)$, where λ_d stands for the largest eigenvalue of A .

We shall now focus our attention on stochastic gradient methods. Let (X_n) be a sequence of random vectors with values in $\mathbb{R}^p$. For a continuously differentiable function f and a given value $\theta_n \in \mathbb{R}^d$, we suppose that we observe or we are able to evaluate a random vector $H(\theta_n, X_{n+1})$ such that

$$\mathbb{E}[H(\theta_n, X_{n+1}) | \mathcal{F}_n] = \nabla f(\theta_n) \quad a.s.$$

where $\mathcal{F}_n$ stands for the σ -algebra of the events occurring up to time n .

Then, in order to find the critical points, in fact the local minima of f , we make use of the stochastic gradient algorithm

$$\theta_{n+1} = \theta_n - \gamma_{n+1} H(\theta_n, X_{n+1}) \quad (2)$$

where the initial value θ_0 can be arbitrarily chosen and (γ_n) is a deterministic positive sequence decreasing toward zero, satisfying

$$\sum_{n=1}^{\infty} \gamma_n = \infty \quad \text{and} \quad \sum_{n=1}^{\infty} \gamma_n^2 < \infty.$$

We clearly have

$$\theta_{n+1} = \theta_n - \gamma_{n+1} \nabla f(\theta_n) + \gamma_{n+1} \varepsilon_{n+1},$$

where $\varepsilon_{n+1} = \nabla f(\theta_n) - H(\theta_n, X_{n+1})$. Consequently, the stochastic gradient algorithm appears as a perturbed discretization of the ordinary differential equation given by (1). We can observe that the stochastic gradient method belongs to the wide family of stochastic algorithms. Moreover, the Robbins–Monro algorithm (Robbins and Monro [4], Robbins and Siegmund [5]) is a very efficient procedure to estimate the zeros of a nonlinear continuous function F . The stochastic gradient algorithm can be seen as a special case of Robbins–Monro algorithm with $F = \nabla f$.

The Kiefer and Wolfowitz algorithm [6,7] was proposed to search the maxima of a strictly concave function f .

It only uses finite difference of perturbed evaluations of the function f . It is given by the recursive relation

$$\theta_{n+1} = \theta_n - \frac{\gamma_{n+1}}{2c_{n+1}} (Y_{n+1} - Z_{n+1}) \quad (3)$$

with

$$\mathbb{E}[Y_{n+1} | \mathcal{F}_n] = f(\theta_n - c_n) \quad \text{and}$$

$$\mathbb{E}[Z_{n+1} | \mathcal{F}_n] = f(\theta_n + c_n) \quad a.s.,$$

where (γ_n) and (c_n) are deterministic positive sequences decreasing to zero such that

$$\sum_{n=1}^{\infty} \gamma_n = \infty, \quad \sum_{n=1}^{\infty} \gamma_n c_n < \infty, \quad \sum_{n=1}^{\infty} \left(\frac{\gamma_n}{c_n} \right)^2 < \infty.$$

A persistently excited version of the Kiefer–Wolfowitz algorithm is the simultaneous perturbation stochastic approximation introduced by Spall [3,8]. A recent survey concerning Spall algorithm as well as some

developments of other finite-difference algorithms along the same lines may be found in Bhatnagar [9]. We also refer the reader to the related contributions of Gerencser [10] and Granichin [11–13].

One can realize that these stochastic algorithms are widely used in many fields such as competitive learning, signal processing, wireless protocol of communication, financial engineering, and stock management.

MAIN RESULTS

Almost Sure Convergence

We start with the simplest situation in which the Robbins–Monro procedure can be applied [4,5].

Theorem 1. *Assume that f is a continuously differentiable function from $\mathbb{R}^d$ to $\mathbb{R}$ and denote by θ^* an isolated critical point of f . In addition, suppose that for all $\theta \neq \theta^*$,*

$$\langle \theta - \theta^*, \nabla f(\theta) \rangle > 0. \quad (4)$$

Consider the stochastic gradient algorithm given by (2), where (γ_n) is a deterministic positive sequence decreasing to zero such that

$$\sum_{n=1}^{\infty} \gamma_n = \infty \quad \text{and} \quad \sum_{n=1}^{\infty} \gamma_n^2 < \infty. \quad (5)$$

If it exists $a > 0$ such that for all $\theta \in \mathbb{R}^d$, $\mathbb{E}[\|H(\theta, X_{n+1})\|^2 | \mathcal{F}_n] \leq a(1 + \|\theta\|^2)$ a.s., then

$$\lim_{n \rightarrow \infty} \theta_n = \theta^* \quad a.s. \quad (6)$$

Assumption (4) indicates that there exists a unique minimum for f , which is also a global minimum. In this situation, the Robbins–Monro algorithm converges almost surely to this global minimum. Similar result is also true for the Kiefer–Wolfowitz algorithm under suitable assumptions [6,7]. One can obtain the optimal rates of convergence by averaging [14]. In a more general setting, Polyak and Tsybakov [15] have also investigated the optimal rates of convergence when considering not only a function f but also a class of smooth functions.

Hereafter, we consider a more general situation Brandiere [16], Brandiere and Duflo [17], Lazarev [18], Pemantle [19] leading to less precise results.

Theorem 2. *Assume that f is a twice continuously differentiable function from $\mathbb{R}^d$ to $\mathbb{R}$ and denoted by Θ^* the set of all critical points of f . Assume that Θ^* is made of isolated points and that*

$$\lim_{\|\theta\| \rightarrow \infty} |f(\theta)| = \infty.$$

In addition, suppose that for any $\theta^ \in \Theta^*$, either the Hessian matrix $\nabla^2 f(\theta^*)$ is positive definite, which indicates that θ^* is a nondegenerate local minimum of f , or that it exists at least a direction $v^* \in \mathbb{R}^d$ depending on θ^* , such that $\langle v^*, \nabla^2 f(\theta^*) v^* \rangle < 0$, which indicates that θ^* is a saddle point or a local maximum of f . Consider the stochastic gradient algorithm given by (2), where the sequence (γ_n) satisfies (5). Assume that it exists $a > 0$ such that for all $\theta \in \mathbb{R}^d$, $\mathbb{E}[\|H(\theta, X_{n+1})\|^2 | \mathcal{F}_n] \leq a(1 + \|\theta\|^2)$ a.s. Furthermore, assume that it exists $c > 0$ such that for all unit $v \in \mathbb{R}^d$*

$$\mathbb{E}[\langle \varepsilon_{n+1}, v \rangle | \mathcal{F}_n] \geq c > 0, \quad (7)$$

where $\varepsilon_{n+1} = H(\theta_n, X_{n+1}) - \nabla f(\theta_n)$, which indicates that the random noise ε_{n+1} weights all possible directions of $\mathbb{R}^d$. Then,

$$\lim_{n \rightarrow \infty} \theta_n = \theta^* \quad \text{a.s.}, \quad (8)$$

where the random vector θ^ belongs to the set of the local minima of f in Θ^* .*

Theorem 2 gives a reasonable condition to ensure that the algorithm converges to a local minimum avoiding saddle points or local maxima. Assumption (7) indicates that there is always noise in an unstable direction of any saddle point or maximum. One way to realize this condition is to add an artificial Gaussian noise in all directions.

Central Limit Theorem

In all the sequel, denoted by

$$\mathcal{C}(\theta^*) = \{\theta_n \rightarrow \theta^*\}$$

the event corresponding to the convergence of the stochastic gradient algorithm to θ^* . The asymptotic normality of the gradient algorithm requires more conditions on the function f and on the step size γ_n . It was established by Fabian [20] for the Robbins–Monro algorithm and Bouton [21] in a more general framework, see also Kushner and Huang [22] and Major and Revesz [23].

We shall restrict ourselves to the particular case where $\gamma_n = \gamma/n$ with $\gamma > 0$.

Theorem 3. *Assume that f is a twice continuously differentiable function from $\mathbb{R}^d$ to $\mathbb{R}$ and denoted by θ^* an isolated critical point of f . In addition, suppose that for all $\theta \neq \theta^*$,*

$$\nabla f(\theta) = \nabla^2 f(\theta^*)(\theta - \theta^*) + O(\|\theta - \theta^*\|^2), \quad (9)$$

where the Hessian matrix $\nabla^2 f(\theta^)$ is positive definite. More precisely, assume that its minimum eigenvalue λ satisfies $\lambda > \zeta$, where $\zeta = 1/(2\gamma)$. If it exists some constant $b > 2$ such that*

$$\sup_{n \geq 1} \mathbb{E}[\|\varepsilon_{n+1}\|^b | \mathcal{F}_n] < \infty \quad \text{a.s.} \quad (10)$$

and

$$\lim_{n \rightarrow \infty} \mathbb{E}[\varepsilon_{n+1} \varepsilon'_{n+1} | \mathcal{F}_n] = \Gamma \quad \text{a.s.}, \quad (11)$$

where $\varepsilon_{n+1} = H(\theta_n, X_{n+1}) - \nabla f(\theta_n)$, and Γ is a positive-definite covariance matrix, then we have on $\mathcal{C}(\theta^)$, the asymptotic normality*

$$\sqrt{n}(\theta_n - \theta^*) \xrightarrow{\mathcal{L}} \mathcal{N}(0, \gamma \Sigma), \quad (12)$$

where the limiting covariance matrix Σ is the solution of the Lyapunov equation

$$(\nabla^2 f(\theta^*) - \zeta I_d) \Sigma + \Sigma (\nabla^2 f(\theta^*) - \zeta I_d) = \Gamma.$$

Remark 1. The solution of the Lyapunov equation is given by

$$\Sigma = \int_0^\infty \exp(-t(\nabla^2 f(\theta^*) - \zeta I_d)) \Gamma \exp(-t(\nabla^2 f(\theta^*) - \zeta I_d)) dt.$$

Theorem 3 also holds in the particular case where $\gamma_n = \gamma/n^\alpha$ with $\gamma > 0$ and $1/2 < \alpha < 1$.

Remark 2. It could be possible to obtain the asymptotic efficiency for the stochastic gradient algorithm by choosing the matrix step size

$$\gamma_n = \frac{(\nabla^2 f(\theta^*))^{-1}}{n}.$$

In this particular situation that is not far from Newton's stochastic algorithm, we can deduce from Kushner and Yin ([24] p. 302) that θ_n is an asymptotically efficient estimator of θ^* with

$$\sqrt{n}(\theta_n - \theta^*) \xrightarrow{\mathcal{L}} \mathcal{N}(0, (\nabla^2 f(\theta^*))^{-1/2} \Sigma (\nabla^2 f(\theta^*))^{-1/2}).$$

However, in most cases, it is not possible to explicitly calculate $\nabla^2 f(\theta^*)$.

The asymptotic normality given by (12) allows to build confidence intervals around the value of θ^* . It only requires the estimation of the limiting covariance matrix Σ . We will see in the following text that the quadratic strong law enables us to compute such an estimate.

Almost Sure Central Limit Theorem

We shall now focus our attention on the law of iterated logarithm given by Gaposhkin and Krasulina [25] and the quadratic strong law established by Pelletier [26] associated with the stochastic gradient algorithm.

Theorem 4. *Under the same assumptions as in Theorem 3, we have almost surely on $\mathcal{C}(\theta^*)$ and for all eigenvectors $v \in \mathbb{R}^d$ of the Hessian matrix $\nabla^2 f(\theta^*)$.*

$$\begin{aligned} \limsup_{n \rightarrow \infty} \left(\frac{n}{2 \log \log n} \right)^{1/2} \langle v, \theta_n - \theta^* \rangle \\ = - \liminf_{n \rightarrow \infty} \left(\frac{n}{2 \log \log n} \right)^{1/2} \langle v, \theta_n - \theta^* \rangle \\ = \sqrt{\gamma v' \Sigma v} \quad a.s. \end{aligned} \quad (13)$$

In particular,

$$\limsup_{n \rightarrow \infty} \left(\frac{n}{2 \log \log n} \right) \|\theta_n - \theta^*\|^2 \leq \gamma \text{tr}(P' \Sigma P) \quad a.s., \quad (14)$$

where P is the orthogonal matrix whose columns are the eigenvectors of $\nabla^2 f(\theta^*)$. Finally, almost surely on $\mathcal{C}(\theta^*)$, we have the quadratic strong law

$$\lim_{n \rightarrow \infty} \frac{1}{\log n} \sum_{k=1}^n (\theta_k - \theta^*)(\theta_k - \theta^*)' = \gamma \Sigma \quad a.s. \quad (15)$$

An easy way to estimate the covariance matrix in (12) is to make use of the quadratic strong law (15) replacing θ^* by θ_n .

Remark 3. Theorem 4 is also true in the particular case where $\gamma_n = \gamma/n^\alpha$ with $\gamma > 0$ and $1/2 < \alpha < 1$, as soon as $\alpha b > 2$. This is of course immediately satisfied if $b \geq 4$. According to Pelletier [26], it is much more appropriate to make use of $\gamma_n = \gamma/n$. As a matter of fact, if $\gamma_n = \gamma/n^\alpha$, the quadratic strong law (15) becomes

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{1}{n^{1-\alpha}} \sum_{k=1}^n (\theta_k - \theta^*)(\theta_k - \theta^*)' \\ = \frac{\gamma}{1-\alpha} \Sigma \quad a.s. \end{aligned} \quad (16)$$

As $\log n$ is always lesser than $n^{1-\alpha}$, the choice $\gamma_n = \gamma/n$ outperforms the second one.

The almost sure central limit theorem was established by Pelletier [27], see Cenac and Cenac [28] for a recent contribution on the convergence of moments.

Theorem 5. *Under the same assumptions as in Theorem 4, we have almost surely on $\mathcal{C}(\theta^*)$, the almost sure central limit theorem*

$$\frac{1}{\log n} \sum_{k=1}^n \frac{1}{k} \delta_{\sqrt{k}(\theta_k - \theta^*)} \Rightarrow \mathcal{N}(0, \gamma \Sigma) \quad a.s. \quad (17)$$

Remark 4. We can observe that the quadratic strong law given by (15) is simply the convergence of the second moment in (17). In addition, for any continuous function h from $\mathbb{R}^d$ to $\mathbb{R}$ such that for some constant $c > 0$, $|h(x)| \leq c(1 + \|x\|^2)$, we have almost surely on $\mathcal{C}(\theta^*)$,

$$\lim_{n \rightarrow \infty} \frac{1}{\log n} \sum_{k=1}^n \frac{1}{k} h(\sqrt{k}(\theta_k - \theta^*)) = \mathbb{E}[h(Z)] \quad a.s.,$$

where Z stands for a random vector with $\mathcal{N}(0, \gamma \Sigma)$ distribution.

EXAMPLES

Least-Square Approximation

Assume that we observe an input–output relationship

$$Y = F(X) + \xi,$$

where $X \in \mathbb{R}^p$ is the input, $Y \in \mathbb{R}$ is the output, and ξ is the driven noise. The link function F is unknown and we look for an approximation of F from a basis of functions $(\varphi_1, \dots, \varphi_d)$ from $\mathbb{R}^p$ to $\mathbb{R}$. We can modelize the input as random vectors and thus we want to minimize, for instance,

$$f(\theta) = \frac{1}{2} \mathbb{E}[(Y - \langle \theta, \Phi(X) \rangle)^2],$$

where

$$\Phi(X) = \begin{pmatrix} \varphi_1(X) \\ \vdots \\ \varphi_d(X) \end{pmatrix}.$$

We suppose that Y and $\Phi(X)$ are square integrable. We clearly have

$$\begin{aligned} \nabla f(\theta) &= -\mathbb{E}[(Y - \langle \theta, \Phi(X) \rangle) \Phi(X)] \quad \text{and} \\ \nabla^2 f(\theta) &= \mathbb{E}[\Phi(X) \Phi(X)']. \end{aligned}$$

Assume that the matrix $\mathbb{E}[\Phi(X) \Phi(X)']$ is positive definite and denoted by θ^* the minimizer of the function f , which is the solution of the equation

$$\mathbb{E}[\Phi(X) \Phi(X)'] \theta = \mathbb{E}[Y \Phi(X)].$$

We can estimate θ^* by the stochastic gradient algorithm

$$\theta_{n+1} = \theta_n - \gamma_{n+1} (Y_{n+1} - \langle \theta_n, \Phi(X_{n+1}) \rangle) \Phi(X_{n+1}),$$

where (X_n, Y_n) is a sequence of independent random vectors sharing the same distribution as (X, Y) . All the results of the previous section are satisfied under additional moment conditions.

Empirical Quantiles

Let X be a random variable with continuous and strictly increasing distribution function F . We are interested in the estimation of the α -quantile θ_α of F , which satisfies

$$F(\theta_\alpha) = \mathbb{P}(X \leq \theta_\alpha) = \alpha.$$

Consider the function

$$f(\theta) = \int_{-\infty}^{\theta} F(x) dx - \alpha \theta.$$

We clearly have $f'(\theta) = F(\theta) - \alpha$ and θ_α is the unique minimum of f . In addition, if $H(\theta, X) = I_{\{X \leq \theta\}} - \alpha$, we can immediately see that $\mathbb{E}[H(\theta, X)] = f'(\theta)$. Consequently, for any $0 < \alpha < 1$, we can estimate θ_α by the gradient descent algorithm

$$\theta_{n+1} = \theta_n - \gamma_{n+1} (I_{\{X_{n+1} \leq \theta_n\}} - \alpha),$$

where (X_n) is a sequence of independent random variables sharing the same distribution as X . As before, all the results of the previous section are satisfied.

Maximum Likelihood Estimation

Let X be a random vector with values in $\mathbb{R}^p$. Assume that the distribution function F_θ of X depends on an unknown parameter $\theta \in \mathbb{R}^d$ and let $\varphi(\theta, \cdot)$ be the probability density function associated with X . In what follows, suppose that the function $\varphi(\theta, \cdot)$ is known. Our goal is to find θ^* that maximizes $\mathbb{E}[\log \varphi(\theta, X)]$. This maximization problem is of course the same as the minimization of $-\mathbb{E}[\log \varphi(\theta, X)]$. Denote

$$H(\theta, X) = \nabla \log \varphi(\theta, X) = \frac{\nabla \varphi(\theta, X)}{\varphi(\theta, X)},$$

where the gradient is taken with respect to θ and suppose that

$$\mathbb{E}[H(\theta^*, X)] = \nabla f(\theta^*) = 0.$$

Moreover, denote by $I(\theta)$ the Fisher information matrix

$$I(\theta) = \mathbb{E}[\nabla \log \varphi(\theta, X) (\nabla \log \varphi(\theta, X))']$$

and assume that $I(\theta^*)$ is positive definite. If the maximum likelihood estimator of θ is very complicated to calculate, we can estimate θ^* by the stochastic gradient algorithm

$$\theta_{n+1} = \theta_n + \gamma_{n+1} H(\theta_n, X_{n+1}),$$

where (X_n) is a sequence of independent random vectors sharing the same distribution as X . Under some regularity assumptions, all the results of the previous section are satisfied. We can also make use of a Newton-like stochastic algorithm

$$\theta_{n+1} = \theta_n + \gamma_{n+1} I(\theta_n)^{-1} H(\theta_n, X_{n+1}),$$

which performs pretty well as in the deterministic case.

Quantization

Quantization is a field where the stochastic gradient is the most used method. Let us explain what is quantization as in Graf and Luschgy [29]. We assume that a phenomenon is well described by a continuous random vector X with values in $\mathbb{R}^p$.

In order to drastically simplify the information contained in X , for example, in view of transmission, we look for a code book with finitely many values that represents, as faithfully as possible, the random vector X . Hence, our goal is to find a discrete random vector Y with q values, which minimizes the quadratic distance

$$\mathbb{E}[\|X - Y\|^2] = \min_{\theta, P} \mathbb{E} \left[\sum_{i=1}^q \|X - \theta_i\|^2 I_{P_i} \right],$$

where $\theta = (\theta_1, \dots, \theta_q) \in (\mathbb{R}^p)^q$ is associated with the discrete values of Y and $P \in \mathcal{P}$ is a partition of the probability space. We can easily observe that, for a given $\theta \in \mathbb{R}^{pq}$, the best choice for P is the Voronoï partition associated with θ , that is $V = (V_1, \dots, V_q)$, where

$$V_i = \left\{ x \in \mathbb{R}^p / \min_{1 \leq k \leq q} \|x - \theta_k\|^2 = \|x - \theta_i\|^2 \right\}.$$

Consequently, our goal is to minimize

$$f(\theta) = \frac{1}{2} \mathbb{E} \left[\sum_{i=1}^q \|X - \theta_i\|^2 I_{V_i}(X) \right],$$

where $V = (V_1, \dots, V_q)$ is the Voronoï partition associated with θ , so that f is well defined as a function of θ . Such minimizers θ^* are called *optimal quantizers* and generally are not unique.

In the particular case $p = 1$, if we know the probability distribution of X , for example, exponential, normal, or Gamma distribution, we can use a deterministic gradient method, namely, the Newton algorithm, in order to find optimal quantizers very accurately.

As soon as $p \geq 2$, we cannot use such an algorithm, because of the high complexity of the Voronoï partition. Therefore, an alternative is to make use of the stochastic gradient algorithm. It is given, for all $1 \leq i \leq q$, by

$$\theta_{i,n+1} = \theta_{i,n} - \gamma_{n+1} (\theta_{i,n} - X_{n+1}) I_{V_{i,n}}(X_{n+1}),$$

where (X_n) is a sequence of independent random vectors sharing the same distribution as X and $V_n = (V_{1,n}, \dots, V_{q,n})$ is the Voronoï partition associated with θ_n .

We can observe that, from step n to step $n + 1$, only one quantizer is modified. It is precisely the one for which X_{n+1} falls in the Voronoï cell.

The quantization can be extended to stochastic processes. Once again, stochastic gradient algorithm in Hilbert spaces is the most popular way to find a numerical approximation of optimal quantizers.

SUMMARY

The method of gradient descent was probably introduced by Cauchy in early nineteenth century with Cauchy's intermediate value theorem. In the middle of nineteenth century, pushed by economy, the optimization became a very important field of mathematics. During all the first part of the twentieth century, scientific advances arose. One of the pioneers in this area was Hotelling [30] who proposed an experimental way to find the value θ^* for which an unknown polynomial function f reaches a maximum or minimum.

At the half of twentieth century, optimization in a random framework appears in various domains: physics, chimics, transmission of information, etc., leading to a

new development of optimization techniques: stochastic optimization such as stochastic gradient methods.

Since the seminal work of Robbins and Monro [4], a wide range of literature is available on stochastic gradient methods. It is very difficult to provide an exhaustive list of references on this domain of applied mathematics.

We refer the reader to the excellent books of Benveniste et al. [31], Duflo [32], Hall and Heyde [33], Kushner and Yin [24], Ljung et al. [34], and Spall [3], and the references therein. A whole history remains to be written. We strongly believe that it is possible to provide much more applications of stochastic gradient methods in applied mathematics.

INTRODUCTION

Genetic algorithms (GAs) [1,2] are stochastic optimization methods inspired by natural evolution and genetics. GAs work with a population or multiset of candidate solutions. Maintaining a *population of candidate solutions*—as opposed to a *single solution*—has several advantages. For example, using a population allows simultaneous exploration of multiple basins of attraction, it allows statistical decision making based on the entire sample of promising solutions even when the evaluation procedure is affected by external noise, and it enables the use of learning techniques for identifying problem regularities. The initial population is typically generated at random using the uniform distribution over all admissible solutions. The population is then updated for a number of iterations using the operators of selection, variation, and replacement. The selection operator ensures that the search for the optimum focuses on candidate solutions of high quality. Variation operators exploit information from the best solutions found so far to generate new high quality solutions. Finally, the replacement operator provides a method for updating the original population of solutions using the new solutions created by selection and variation.

Over the last few decades, GAs have been successfully applied to many problems of business, engineering, and science. Because of their operational simplicity and wide applicability, genetic algorithms are now playing an increasingly important role in computational optimization and operations research.

The purpose of this article is to provide an introduction to GAs. The article is organized as follows. The section titled “Genetic Algorithm Procedure” outlines the basic GA procedure. The section titled “Genetic Algorithm Operators” details popular GA operators and discusses how GAs can be applied to problems defined over various representations. The section titled “Dealing with Multiple Objectives, Constraints, and Noise” focuses on the use of GAs for solving problems with multiple objectives, noise, and constraints. The section titled “Efficiency Enhancement” outlines several approaches to enhancing efficiency of GAs. The section titled “Guidelines for Applying Genetic Algorithms to a New Problem” provides basic guidelines for applying GAs to a new problem. Finally, the section titled “Starting Points for Obtaining Additional Information” outlines some of the main starting points for the reader interested in learning more about GAs.

GENETIC ALGORITHM PROCEDURE

An optimization problem may be defined by specifying (i) a representation of potential solutions to the problem and (ii) a measure for evaluating quality of each candidate solution. The goal is to find a solution or a set of solutions that perform best with respect to the specified measure. For example, in the traveling salesman problem, potential solutions are represented by permutations of cities to visit and the measure of solution quality gives preference to shorter tours.

GAs pose no hard restrictions on the representation of candidate solutions or the measure for evaluating solution quality, although it is important that the underlying representation is consistent with the chosen operators. Representations can vary from binary strings to vectors of real numbers, to permutations, to production rules, to schedules, and to program codes. Performance measures can be based on a computer procedure, a simulation, an interaction with the human, or a

combination of the above. Solution quality can also be measured using a partial ordering operator on the space of candidate solutions, which only compares relative quality of two solutions without expressing solution quality numerically. In addition, evaluation can be probabilistic and it can be affected by external noise. Nonetheless, for the sake of simplicity, in this section it is assumed that candidate solutions are represented by binary strings of fixed length and that the performance of each candidate solution is represented by a real number called *fitness*. The task is to find a binary string or a set of binary strings with the highest fitness.

Components of a Genetic Algorithm

The basic GA procedure consists of the following key ingredients:

Initialization. GAs usually generate the initial population of candidate solutions randomly according to a uniform distribution over all admissible solutions. However, the initial population can sometimes be biased using prior problem-specific knowledge or other optimization procedures [3–6].

Selection. Each GA iteration starts by selecting a set of promising solutions from the current population based on the quality of each solution. A number of different selection techniques can be used [7,8], but the basic idea of all these methods is the same—make more copies of solutions that perform better at the expense of solutions that perform worse. For example, *tournament selection* of order s selects one solution at a time by first choosing a random subset of s candidate solutions from the current population and then

selecting the best solution out of this subset [9]. Random tournaments are repeated until there are sufficiently many solutions in the selected population. The size of the tournaments determines selection pressure—the larger the tournaments, the higher the pressure on the quality of each solution. The tournament size of $s = 2$ is a common setting. Typically, the size of the selected set of solutions is the same as the size of the original population.

Variation. Once the set of promising solutions has been selected, new candidate solutions are created by applying recombination (crossover) and mutation to the promising solutions. Crossover combines subsets of promising solutions by exchanging some of their parts. Mutation perturbs the recombined solutions slightly to explore their immediate neighborhood. Most of the commonly used crossover operators combine pairs of promising solutions. For example, *one-point crossover* randomly selects a single position in the two strings (crossing site) and exchanges the bits on all the subsequent positions (see Fig. 1). Typically, the selected population is first randomly divided into pairs of candidate solutions, and crossover is then applied to each of these pairs with a specified probability p_c . The probability p_c of crossover is usually in the range $[0.6, 0.95]$. One of the most common mutation operators for binary strings is *bit-flip mutation*, in which each bit is modified (flipped) with the same probability (see Fig. 1); the probability of changing a bit is typically small, changing only one or a few bits at a time.

Figure 1. In one-point crossover, a site is randomly chosen and the strings exchange all bits after this site. In bit-flip mutation, each bit is modified with the same probability. The probability is typically small and only one or a few bits are changed.

Replacement. After applying crossover and mutation to the set of promising solutions, the population of new candidate solutions replaces the original one or its part, and the next iteration is executed (starting with selection) unless termination criteria are met. For example, the run can be terminated when the population converges to a singleton, the population contains a good enough solution, or an upper bound on the number of iterations has been reached.

The pseudocode of the basic genetic algorithm is as follows:

```
Genetic algorithm {
  t = 0;
  generate initial population P(0);
  while (not done) {
    select population of promising solutions
      S(t) from P(t);
    apply variation operators on S(t) to
      create O(t);
    create P(t+1) by combining O(t) and P(t);
    t = t+1;
  }
}
```

Since genetic algorithms are inspired by biology, common GA terminology is strongly influenced by that in biology; see Table 1 for an overview of GA terminology.

Table 1. Common GA Terminology

Term	Alternative Name(s)
Candidate solution	Individual, chromosome, string
Decision variable	Variable, locus, string position
Value of decision variable	Bit, allele
Measure of solution quality	Fitness function, objective function
Numeric representation of solution quality	Fitness, fitness value
Population of promising solutions, $S(t)$	Parent population, parents, selected solutions
Population of new solutions, $O(t)$	Offspring population, offspring, children
Iteration	Generation

Simulation of a Genetic Algorithm by Hand

To illustrate the basic GA procedure, consider solving the onemax problem, which assumes that candidate solutions are represented by binary strings of n bits, and the fitness is computed as the sum of bits in the input binary string:

$$\text{onemax}(X_1, X_2, \dots, X_n) = \sum_{i=1}^n X_i,$$

where $(X_1, X_2, \dots, X_n)$ denotes the input binary string. onemax is a simple unimodal function with the optimum in the string $(1, 1, \dots, 1)$.

The simulation will use binary tournament selection (i.e., $s = 2$), one-point crossover, bit-flip mutation and full replacement (the new population of solutions fully replaces the original population). The remaining parameters of the simulation by hand will be set as follows:

Parameter	Description	Value
n	String length	8
N	Population size	10
p_c	Crossover probability	0.6
p_m	Mutation probability	1/8

The first step consists of generating $N = 10$ binary strings of length $n = 8$. The resulting initial population is shown below:

	Candidate Solution	Fitness
1	10111001	5
2	00010010	2
3	01101001	4
4	00001001	2
5	00100110	3
6	00001010	2
7	11011000	4
8	11111000	5
9	11111000	5
10	00011001	3

4 GENETIC ALGORITHMS

Selection of the parent population starts by random selection of 10 pairs of candidate solutions from the original population. The winner of each of these tournaments is selected based on the fitness function (for ties the winner is chosen arbitrarily):

Tournament	Winner	Fitness
1 11111000 & 00011001	11111000	5
2 00010010 & 00011001	00011001	3
3 11011000 & 10111001	10111001	5
4 01101001 & 00001010	01101001	4
5 00100110 & 11111000	11111000	5
6 00010010 & 11111000	11111000	5
7 01101001 & 10111001	10111001	5
8 00001001 & 00010010	00010010	2
9 00100110 & 11011000	11011000	4
10 10111001 & 00011001	10111001	5

Since each parent solution was chosen independently, it is not necessary to pair solutions for crossover randomly, but consequent pairs of selected strings can be considered for crossover. There are five pairs of parents and the probability of crossover is 0.6; therefore, about three pairs of parents are expected to be recombined using crossover. Mutation is then applied to all the resulting strings. Mutation is expected to change 1 bit on average since $p_m = 1/8$ and $n = 8$. The results after applying crossover follow:

Parents	Crossing Site	After Crossover
1 11111000	3	11011001
2 00011001		00111000
3 10111001	—	10111001
4 01101001		01101001
5 11111000	2	11111000
6 11111000		11111000
7 10111001	—	10111001
8 00010010		00010010
9 11011000	6	11011001
10 10111001		10111000

The results of applying mutation to the resulting population follow:

	After Crossover	After Mutation	Fitness
1	11011001	11111001	6
2	00111000	00111000	3
3	10111001	11111001	6
4	01101001	00111101	5
5	11111000	11110000	4
6	11111000	11111000	5
7	10111001	10011011	5
8	00010010	10010010	3
9	11011001	11010001	4
10	10111000	10111000	4

The population after mutation will then replace the original population of solutions, which serves as the starting point for the next GA iteration.

One of the ways to analyze the results of the simulation is to look at the change in the average fitness of the population. The average fitness of the original population is 3.5, whereas the average fitness of the new population is 4.5. Therefore, one round of selection, crossover, and mutation increased the average quality of solutions in the population. At the same time, most of the new solutions are different from those in the original population, although they share many similarities. We were thus able to create a population of new solutions, which are of better quality than those that we started with. Simulating the following few iterations of the GA should further increase solution quality, until the global optimum would be found.

Simulation of a Genetic Algorithm on a Larger Problem

In this section, the simulation of the GA by hand is extended to deal with a larger Onemax problem of $n = 100$ bits. Due to the increased problem size, in order to ensure that the global optimum is found with a high probability, we also increase the population size. Specifically, we set the population size as $N = 100$, the probability of crossover as

Figure 2. GA simulation on onemax of $n = 100$ bits: (a) fitness values and (b) proportions of 1s in different positions.

$p_c = 0.6$, and the probability of mutation as $p_m = 1/100$. The results of the simulation are presented in Fig. 2.

The results presented in Fig. 2a show that the average population fitness increases over time and so does the maximum and minimum fitness in the population, although the minimum and maximum fitness often decrease temporarily. Furthermore, Fig. 2b shows that the proportions of 1s in most string positions increase over time, although some of these proportions decrease temporarily and fluctuate substantially. Nonetheless, the average proportion of 1s in different positions steadily increases and eventually the probability of a 1 in any position becomes 80% or more. Continuing the simulation would lead to a further increase in the proportions of 1s until almost every solution in the population would be globally optimal.

Of course, onemax is a relatively simple problem and it is not a surprise that GAs can solve this problem without any difficulty. Onemax is used to only illustrate the basic GA procedure on a problem that is easy to understand. For onemax, theoretical models [10–12] exist which estimate that, assuming that the expected number of bits that do not converge to the correct values is upper bounded by an arbitrary constant, the number of evaluations until convergence is expected to grow at most as $O(n \log n)$ where n is the number of bits in the problem.

GENETIC ALGORITHM OPERATORS

Previous section presented the basic GA procedure and some of the simplest GA operators. This section presents several other popular selection, replacement, and variation operators. In addition, the section discusses how GAs can be used to solve problems where candidate solutions are not represented by fixed-length binary strings and how linkage learning can be incorporated into GAs to improve their performance and scalability.

Selection

The main task of the selection operator is to select a population of promising candidate solutions from the current population of candidates, ensuring that solutions of higher quality have a higher probability of being selected than others. There are two main types of selection methods: (i) fitness proportionate selection, and (ii) ordinal selection.

Fitness Proportionate Selection. In the *fitness proportionate selection* methods, each selected solution is drawn from the same probability distribution and the probability of selecting the solution is in some way proportional to its fitness value. Most commonly, the fitness is assumed to be positive and the probability of selecting an individual X with

fitness $f(X)$ is linearly proportional to its fitness. Therefore, the probability $p_{\text{select}}(X)$ of selecting X from population $P(t)$ is

$$p_{\text{select}}(X) = \frac{f(X)}{\sum_{Y \in P(t)} f(Y)}.$$

Ordinal Selection. In *ordinal selection* methods, the probability of selecting a particular member of the population does not directly depend on the actual value of its fitness but it depends on the relative quality of this solution compared to other members of the current population. *Tournament selection* discussed in the previous section is one of the most popular ordinal selection methods [9]. Another popular ordinal selection method is *truncation selection*, which selects a given percentage τ of the best solutions from the population [11]. For example, for $\tau = 0.5$, the best half of the population is selected. If the selected population should have the same size as the original, multiple copies of each candidate solution in the selected portion of the population can be created.

Ordinal selection methods are invariant to linear transformations of fitness and they pose fewer restrictions on the fitness function than fitness proportionate selection methods do. In addition, ordinal selection methods exert a sustained pressure toward solutions of higher quality and the strength of this pressure is often easier to control. These are the main reasons why ordinal selection methods are generally more popular than fitness proportionate selection methods.

The selection operator can also be used to promote population diversity by adjusting the probability of selecting each candidate solution based on how this solution differs from the solutions that have already been selected. To promote diversity, preference should be given to solutions that differ from the solutions selected so far. The methods that aim at maintaining diversity of GA populations are often referred to as *nicing methods* [13–16].

One of the most popular approaches to niching via selection is *fitness sharing*, in

which fitness values are updated so that the individuals similar to the previously selected individuals are penalized [13,15–18].

Replacement

The main task of the replacement operator is to incorporate the population of new candidate solutions into the original population of candidates. There are two main approaches to replacement: (i) delete-all and (ii) steady state.

Delete-All or Full Replacement. With delete-all or full replacement, the entire original population is replaced with the new solutions as was done in the simulations presented in the previous section.

Steady-State Replacement. It may often be beneficial to allow candidate solutions in the original population to become a part of the new population, providing overlap between the populations in subsequent iterations of the GA. One way to accomplish this is to combine the original population of candidate solutions with the newly generated ones, and then select the best solutions out of the combined population to form the population for the next iteration. Another approach is to use selection and variation to create fewer individuals than is the size of the original population, and then replace only some of the original solutions with the new ones. The solutions to replace may be selected at random or they may be chosen to be the worst solutions in the original population. GAs where the best solutions found so far are guaranteed to survive to the next iteration are often referred to as *elitist* GAs. The proportion of the population that is going to be replaced by new individuals is typically called *generation gap*. GAs with small generation gap in which a substantial portion of the original population survives to the next generation are often called *steady-state* GAs. In practice, steady-state replacement schemes are more popular than delete-all replacement.

Replacement can also be used to promote diversity in the population and ensure that the populations of candidate solutions represent a diverse sample of candidate solutions. For example, in a crowding factor model (or, more simply, crowding) [19], for each new individual, a subset of CF candidate solutions is first selected from the original population. The new solution then replaces the most similar solution from this subset. The parameter CF is called *crowding factor*. The crowding factor provides a way to control crowding; the higher the value of CF , the stronger the pressure on diversity maintenance. Another replacement strategy that promotes diversity is called *restricted tournament selection* [20]. Restricted tournament selection proceeds similar to crowding; however, the most similar solution from the selected subset is replaced only if the new solution is better (with respect to the fitness function).

Variation

One-point crossover and bit-flip mutation are among the simplest and most popular variation operators. However, many other variation operators are common in practice. This subsection reviews a few such operators applicable to candidate solutions represented by binary strings with the focus on crossover operators applicable to two parents. The topic of variation is revisited in the sections titled “Dealing with Other Representations” and “Adaptive Operators and Linkage Learning,” which discuss linkage learning and some of the more advanced variation operators.

One-Point, Two-Point and k -Point Crossover. In *one-point crossover*, a crossing site is chosen at random and the two parents exchange all bits after the selected position. In *two-point crossover*, two crossing sites are randomly selected and the two parents exchange all bits between these two sites. The two-point crossover can be further generalized to k -point crossover, in which k crossing sites are selected. Two-point crossover can be approximated by two applications of one-point crossover, whereas k -point crossover can be approximated by k -

applications of one-point crossover. Most frequently, one-point or two-point crossover operators are used.

Uniform Crossover. *Uniform crossover* exchanges the bits in each position of the two parents with probability 50%. About half of the bits are expected to be exchanged on average.

The main difference between k -point crossover and uniform crossover lies in the way these operators select the positions in which the bits are going to be exchanged. In one-point crossover or, more generally, in k -point crossover there is an implicit linkage between positions located close to each other in solution strings. This is because positions that are close to each other are likely to be treated together (either exchanged or not). On the other hand, uniform crossover treats every string position independently, and it is therefore independent of the ordering of decision variables in the solution strings. The topic of linkage in crossover will be revisited in section titled “Adaptive Operators and Linkage Learning.”

It is of note that in GAs crossover is often considered the primary variation operator [2,21], whereas in evolution strategies [22,23] mutation is considered the primary variation operator. Consequently, the probability of crossover in GAs is typically quite high (60% or more) and the strength of mutation is set so that mutation causes only small changes in the solution. For an introduction to evolution strategies, see Bäck *et al.* [24] and Beyer and Schwefel [25].

Dealing with Other Representations

In practice, candidate solutions are often not represented as binary strings of fixed length; for example, candidate solutions may be represented by permutations, vectors of real values, or variable length strings. There are two main approaches to applying GAs to such problems:

Map Binary Strings to the Original Representation. Introduce a mapping from binary strings of fixed length to candidate solutions in the original representation. Then, a standard GA for

binary strings can be applied and the mapping function can be used to map each obtained candidate solution to the original representation so that the solution can be evaluated. In some cases, it may be difficult to design a one-to-one mapping and, as a result, not all admissible solutions will be considered. Another potential complication is that it may sometimes be far from straightforward to design an appropriate mapping between the set of binary strings and the actual problem representation. On the other hand, the mapping may introduce additional opportunities for discovery and exploitation of problem regularities, which may not be apparent in the original representation.

Modify Variation Operators. Modify variation operators to make them work with the other representation. Extensions of standard variation operators to some representations are straightforward. For example, if candidate solutions are represented by strings over a finite (nonbinary) alphabet, all aforementioned crossover operators can be applied without any modification and the bit-flip mutation can be adjusted to change the value being modified to any other admissible value. Nonetheless, if the used representation is qualitatively different, variation operators may have to be modified.

The remainder of this section discusses the two approaches to dealing with other representations using GAs through examples for two of the most popular representations: (i) real-valued vectors and (ii) permutations.

Mapping between Other Representations and Binary Strings. Solutions to many real-world problems can be encoded as vectors of real-valued variables. There are numerous ways for mapping real-valued vectors into binary strings and the other way around; however, since each real-valued variable can obtain infinitely many values, the mapping cannot be one-to-one and some accuracy will have to be lost when representing real-valued vectors using binary strings of fixed

length. For simplicity, let us assume that each real-valued variable can obtain values from $[a, b]$ where $a < b$, and the task is thus to represent vectors from $[a, b]^n$ where n is the number of real-valued variables.

One way to approach this problem is to use a fixed number k of bits to represent each real-valued variable in the vector [2]. Binary strings that represent n real-valued variables would therefore consist of $n \times k$ bits. The k bits for each real-valued variable X_i are interpreted as binary representation of an integer k_i from 0 to $2^k - 1$. The value of X_i for a particular combination of the k bits representing X_i is given by

$$X_i = a + (b - a) \frac{k_i}{2^k - 1}.$$

Before evaluating each binary string, the values of the real-valued variables are obtained, and the resulting real-valued vector is evaluated using the fitness function. One may also consider mapping real-valued vectors to binary strings, where the value of each variable X_i would determine the closest k_i , and, consequently, the most accurate k -bit representation of X_i .

Clearly, the more bits are used to represent each real value, the more accurate the representation becomes. An appropriate value of k depends on the desired accuracy of the solution and the ruggedness of the fitness landscape, but in many cases, one can use between 5 and 30 bits per real variable. The final solutions can be further tuned with a local search method, using for example, a variant of the steepest descent/ascent method.

Intuitively, after several iterations of a GA, most variables will have their values concentrated in one or several smaller areas of the interval $[a, b]$. This is the reason why using a mapping function that assumes that the binary strings can represent only equidistant values becomes inefficient, as most of these values will lead to solutions of low quality and will therefore not be used. Hence one may choose to use an adaptive discretization scheme, in which more points are allocated to subintervals that appear in the population most frequently [26–29].

Figure 3. Partially matched crossover starts by selecting two positions at random. Then, the elements between the two positions are matched against the other parent solution and the corresponding pairs of elements define pairs of elements to exchange in each parent solution. In this example, the elements between the two selected positions are (4, 6, 7) and (5, 2, 8); therefore, in both solutions, 4 will exchange with 5, 6 will exchange with 2, and 7 will exchange with 8.

Binary strings can also be used to encode candidate solutions from other representations, such as permutations, tree graphs, or combinations of several different representations. Although there are certain benefits of mapping a particular representation to binary strings, such as the potential for finding and exploiting various problem regularities, except for the domain of real-valued vectors, practitioners often prefer to use the original representation of the problem to represent candidate solutions and use modified variation operators capable of directly manipulating solutions in the representation used. Some examples for the domain of permutations and real-valued vectors are presented next.

Variation Operators for Permutations and Real-Valued Vectors. Many important optimization problems deal with candidate solutions represented by permutations; examples of such problems include the quadratic assignment problem and the traveling salesman problem. Although the variation operators presented thus far can be applied to permutations, doing this may often result in candidate solutions that are not valid permutations. One way to deal with this problem is to define a *repair operator*, which corrects candidate solutions after variation so that they become valid. Another approach is to modify the variation operators themselves so that only valid permutations are obtained. Two crossover operators and several mutation operators will be presented next, all of which directly manipulate permutations without making them invalid.

Partially Matched Crossover (PMX). PMX [30] combines two parent permutations by first selecting two permutation positions at random. Then, for each permutation element between the two positions, the element is exchanged with the corresponding element in the other parent solution. All exchanges are done in both parent solutions. An illustrative example of the partially matched crossover is shown in Fig. 3.

Uniform Order-Based Crossover. Uniform order-based crossover [31] starts by generating a mask to determine which elements will be copied from the original parent and which will be taken from the other parent permutation. The mask may be defined, for example, by generating a 1 in each position with probability 50% and generating a 0 otherwise. The two parents retain the elements in the positions where the mask contains a 1. The remaining elements are filled in from the other parent in the order they appear in the other parent. An illustrative example is shown in Fig. 4.

Swaps, Inversion, and Scramble Mutation.

Swap mutation starts by selecting two permutation elements at random and it then exchanges these two elements. *Inversion mutation* starts by selecting two locations in the permutation and it then inverts the permutation elements between these two locations. Finally, *scramble mutation* selects two locations at random and it then randomly

Figure 4. Uniform order-based crossover starts by selecting random positions for which the permutation elements do not change. The remaining positions are filled with the missing elements copied in the order they appear in the other parent.

Figure 5. Mutation operators for permutations. All three mutation operators shown here start by randomly selecting two locations in the permutation (in this example, the second and sixth positions are selected). Swap mutation exchanges the elements in the selected locations. Inversion mutation inverts the order of the elements between the two locations. Scramble mutation randomly reorders all the elements between the two locations.

reorders all elements between the two selected positions. All three mutation operators are illustrated in Fig. 5.

Numerous variation operators have been designed for real-valued vectors. We mention a few simple ones here.

Arithmetic Crossover. Arithmetic crossover starts by selecting a location i in the two parents at random and generating a random parameter $\alpha \in [0, 1]$ according to the uniform distribution. Denoting the variable at location i in the first parent by X_i and the corresponding variable in the second parent by Y_i , the values of X_i and Y_i are mapped to X'_i and Y'_i , respectively, as follows:

$$\begin{aligned} X'_i &= (1 - \alpha)X_i + \alpha Y_i, \\ Y'_i &= (1 - \alpha)Y_i + \alpha X_i. \end{aligned}$$

Arithmetic crossover can also be applied to several or even all variables.

Simulated Binary Crossover (SBX). In simulated binary crossover [32], a location for the crossover site is first chosen, similarly as in arithmetic crossover. Let us denote the variables of the two parents for the chosen crossover site by X_i and Y_i , and assume (without loss of generality) that $X_i < Y_i$. The new values of X_i and Y_i are computed as

$$\begin{aligned} X'_i &= \frac{X_i + Y_i}{2} - \frac{\beta}{2} (Y_i - X_i), \\ Y'_i &= \frac{X_i + Y_i}{2} + \frac{\beta}{2} (Y_i - X_i), \end{aligned}$$

where $\beta > 0$ is a randomly generated parameter (spread factor). One way to generate β is to use the following probability density function [32]:

$$c(\beta) = \begin{cases} 0.5(n+1)\beta^n & \text{for } \beta \leq 1 \\ 0.5(n+1)\beta^{-n-2} & \text{for } \beta > 1. \end{cases}$$

This procedure can be applied, similarly as in arithmetic crossover, to several or even all variables in the two parents.

Gaussian Mutation. In Gaussian mutation, each variable is modified by adding a random number according to a Gaussian distribution with zero mean. The variance of the Gaussian distribution defines the strength of mutation, and is typically significantly smaller than the range of values of a variable.

Adaptive Operators and Linkage Learning

The combination of selection and variation is the main driving force in the search for the optimum in a GA. Selection selects the most promising candidate solutions, whereas variation combines parts of the selected candidate solutions and explores their immediate neighborhood. To ensure that the combination of selection and variation enables robust, efficient, and scalable search for the global optimum, it is necessary that variation exploits regularities in the problem landscape and that it combines and modifies the best candidate solutions in a meaningful way. Nonetheless, all variation operators discussed in the previous section process candidate solutions in the same way regardless of the specifics of the problem being solved. Consequently, for some classes of difficult problems, practitioners may often have to either modify these variation operators to better suit the problem or modify the representation of candidate solutions to make the existing variation operators more effective. One way to alleviate this problem is to use *adaptive variation operators* that are capable of adapting to the problem being solved. In this section, we discuss the use of adaptive operators with the main focus on recombination operators capable of *linkage learning* [21,33–35].

The previous section pointed out that in one-point crossover implicit linkage

is introduced on variables encoded in consequent locations of solution strings. Consequently, combinations of values in consequent positions of solution strings are often preserved by variation, whereas combinations of values in positions located far from each other may be often modified. This has a positive effect on GA performance if the decision variables located close to each other are strongly correlated in the problem being solved. Nonetheless, for many problems variable correlations may appear both between variables that are located close to each other and those that are located far away from each other. Furthermore, a practitioner may not be aware of correlations that are important for solving the problem in a scalable manner. This is why practitioners are often forced to define new, problem-specific variation operators or to modify the representation of candidate solutions so that the correlations between problem variables correspond more closely to the implicit linkage introduced by the variation operators used, such as the one-point crossover.

To alleviate this problem, adaptive variation operators can be designed that are capable of discovering the most important interactions between problem variables and modifying the recombination operator accordingly. The process of discovering important interactions between problem variables in order to improve effectiveness of variation is often referred to as *linkage learning* [21,33–37]. The term *linkage* is also common in biological systems, where linkage refers to the level of association in the inheritance of two or more nonallelic genes that is higher than that expected if these genes were independent [38].

There are two main approaches to linkage learning [35]. In the *unimetric approach*, linkage learning is based solely on the fitness values obtained during the GA run. In the *multimetric approach*, linkage learning is based on an additional metric besides the fitness function itself. While unimetric approaches appear more biologically plausible, multimetric approaches have been somewhat more successful in practice [35].

GAs capable of linkage learning can be split into three main categories: (i)

perturbation techniques, (ii) linkage adaptation techniques, and (iii) estimation of distribution algorithms. Linkage adaptation techniques are the only category based on the unimetric approach.

Perturbation Techniques. In perturbation-based linkage learning GAs, linkages are identified via perturbing candidate solutions and analyzing the effects of these perturbations on the fitness values. The main representatives of perturbation-based linkage learning GAs are the messy GA [36,39], the fast messy GA [37,40], the gene expression messy GA [41], the linkage identification by nonmonotonicity detection GA [42,43], and the dependency-structure-matrix-based GA [44,45].

Linkage Adaptation Techniques. In linkage adaptation techniques, linkages are evolved along with candidate solutions. Selection thus remains the main driving force of linkage learning. Linkage adaptation is used, for example, in the linkage learning GA [46].

Estimation of Distribution Algorithms (EDAs). In EDAs [47–50]—also called *probabilistic model-building genetic algorithms* and *iterated density estimation algorithms*—standard variation operators of genetic algorithms are replaced by building and sampling probabilistic models of selected candidate solutions. Since many classes of probabilistic models enable the discovery and use of dependencies between problem variables, the use of probability distributions provides a powerful tool for multimetric linkage learning. Some of the linkage learning GAs based on the EDA framework are the Bayesian optimization algorithm (BOA) [51,52], the estimation of Bayesian networks algorithm (EBNA) [53], the learning factorized distribution algorithm (LFDA) [54], and the extended compact genetic algorithm (ecGA) [55]. For more information on EDAs, please see other literature [47–50].

DEALING WITH MULTIPLE OBJECTIVES, CONSTRAINTS, AND NOISE

Many challenging real-world problems contain multiple objectives or constraints, or the evaluation of solution quality is affected by noise. GAs provide a fairly powerful solution even in these scenarios [56,57]. In fact, robustness and the ability to deal with multimodal, noisy, constrained, and multiobjective optimization problems are among the key advantages of GAs over many other optimization techniques. This section reviews some of the most important concepts for dealing with problems with multiple objectives, noise, and constraints. The main focus is on providing the interested reader with pointers.

Multiobjective Genetic Algorithms

In multiobjective optimization, the task is to maximize or minimize several objectives. For example, in engine design, one may want to maximize performance and minimize fuel consumption. The main difficulty in dealing with multiobjective problems is that the objectives are typically conflicting because increasing solution quality with respect to one objective leads to decreased quality with respect to another objective. There are two basic approaches to solving multiobjective optimization problems using GAs and other evolutionary algorithms [56,57]:

Transform Multiple Objectives into a Single Objective. One way to deal with a multiobjective problem is to transform all objectives into a single objective using a weighted sum, utility theory, or another approach. The main difficulty lies in the appropriate selection of weights or utility functions because there is typically only little problem-specific knowledge to guide these design choices.

Find the Entire Pareto-Optimal Set (Trade-Off between Objectives). Another approach is to find the entire Pareto-optimal set (front) of solutions or a representative subset of the entire Pareto-optimal set [58,59]. A set of candidate solutions is called

Figure 6. In this example, the task is to maximize two objectives and each axis in the graph corresponds to one of these objectives. The two solutions *A* and *B* are members of the Pareto-optimal front (set), and they thus cannot be dominated by any other admissible solution in both objectives. Two solutions *C* and *D* are not members of the Pareto-optimal set, because they are dominated by other solutions. For example, *C* is dominated by *A* and *D* is dominated by *B*.

Pareto optimal if the set contains only solutions that are not dominated (outperformed) by any other admissible solution in all objectives. See Fig. 6 for an illustration of the Pareto-optimal set. The set of Pareto-optimal solutions defines the trade-off between the objectives and can serve as the main input for finding the solution of desired properties. The main difficulty in finding the entire Pareto-optimal set is that the size of the set typically grows very fast with the number of objectives and so does the difficulty of finding enough representatives of this set. Two most popular variants of a GA for finding the Pareto-optimal set of solutions are (i) the nondominated sorting GA-II (NSGA-II) [60], and (ii) the improved strength Pareto evolutionary algorithm (SPEA2) [61]. In both algorithms, the modifications take place in selection and replacement operators; other operators remain the same as in standard, single-objective GAs.

For an excellent introduction to solving multiobjective optimization problems using GAs, see Deb [56] and Coello *et al.* [57].

Noisy Evaluation

In many real-world problems, evaluation of candidate solutions is affected by noise. The sources of noise include physical measurements, approximate models, stochastic simulation models, incomplete information, and human-computer interaction [62].

Genetic and other evolutionary algorithms are known to be capable of dealing with problems that include noise particularly well [62,63]. This is due to several reasons. Most importantly, one of the consequences of using a population of candidate solutions as opposed to a single solution is that the use of a population alleviates the effects of noise by averaging them out. In addition, GAs do not require derivatives or gradients, which are difficult to approximate in the presence of noise.

One way to alleviate the effects of noise in fitness evaluation is to increase the population size [10,21,63]. In addition to the increased population-sizing requirements, in the presence of noise, the overall number of iterations until convergence can be expected to increase [21,63].

Besides increasing the population size and the number of iterations, one may deal with noise by using *fitness averaging*. The main idea of fitness averaging is to evaluate each candidate solution several times, and use the average fitness of these evaluations as the fitness of this solution. Given the available time for the GA and the specifics of the problem, one can compute the optimal number of evaluations for each candidate solution [64].

Constraints

In many real-world optimization problems, the set of admissible solutions is defined

using a set of constraints, which may be defined, for example, by providing lower bounds for linear combinations of variables. The task is to maximize or minimize a given objective function subject to the given constraints.

There are three main types of approaches to using GAs for solving optimization problems with linear or nonlinear constraints:

Preserve the Feasibility of Candidate Solutions. Specialized variation operators may be defined that are always guaranteed to preserve feasibility of candidate solutions. If the initial population is generated so that it contains only feasible solutions and if the specialized variation operators are used, all solutions obtained during the GA run will be guaranteed to be feasible with respect to the given constraints. Assuming that the search space is convex and that the feasible solutions are represented by real-valued vectors, one may use, for example, the genetic algorithm for numerical optimization of constrained problems (GENOCOP) [65]. Another way to ensure feasibility of candidate solutions is to reject infeasible solutions [66] or to control the proportion of infeasible solutions in some way [67]. Finally, one may introduce *repair* operators, which modify each infeasible solution to make it feasible [68].

Penalize the Infeasible Solutions. If the population is allowed to contain solutions that violate some of the constraints, infeasible solutions may be penalized so that the search is biased toward feasible regions of the search space. This can be done, for example, by introducing a static or dynamic penalty function that reduces fitness of infeasible solutions [69–71] or by modifying the selection operator to consider constraint violation in addition to the fitness value [72].

Hybrid Approaches. The above two classes of approaches to solving constrained optimization problems can be combined in various ways, creating hybrid

approaches to dealing with constrained problems.

For an overview of the work on solving optimization problems with constraints using genetic and other evolutionary algorithms, the interested reader should consult Michalewicz and Janikow [65], Coello [73], and Michalewicz [74].

EFFICIENCY ENHANCEMENT

Practical applications of GAs often necessitate the use of additional efficiency enhancement techniques, such as parallelization and hybridization. There are four main categories of efficiency enhancement techniques: (i) parallelization, (ii) hybridization, (iii) evaluation relaxation, and (iv) time continuation. This section reviews these main types of efficiency enhancement techniques.

Parallelization

One way to speed up GAs is to distribute the computation to multiple processors [75–79]. There are three main types of parallel GAs [78]: (i) single-population master-slave GAs, (ii) single-population fine-grained GAs, and (iii) multiple-population coarse-grained GAs (see Fig. 7 for an illustration of these types of parallel GAs).

Single-Population Master-Slave GAs. In the master-slave architecture, the computation is controlled by a master processor, which stores the population and executes GA operators. Slave processors are typically used only to compute the fitness values of candidate solutions. Other GA operators may also be distributed, but due to the relatively high cost of communication between different processors, it is important to ensure that the savings in computational time are more significant than the time required for communication between the master and slave processors.

Single-Population Fine-Grained GAs. Fine-grained GAs consist of one spatially structured population, which is

Figure 7. Illustration of different types of parallel GAs.

distributed among a large number of processing units. Fine-grained GAs are best suited for massively parallel computers. Ideally, each processing unit considers only one candidate solution. Selection and variation are restricted based on the spatial distribution and communication structure of the parallel computer. For example, the individuals may be distributed on a 2D grid and communication may be restricted to consider only four neighbors of each candidate solution.

Multiple-Population Coarse-Grained GAs.

The multiple-population coarse-grained GAs split the population into several subpopulations, which develop in isolation. Infrequent migration of individuals from one subpopulation to another is allowed. There are numerous parameters that define the migration patterns, such as when and how many individuals are exchanged between subpopulations, and which subpopulations are allowed to exchange individuals.

Ideally, if the GA is executed in parallel using p processors, the speedup compared to the standard GA implementation on a single processor should be approximately p or even more; otherwise, the computational resources are not used efficiently. For introduction and theoretical guidelines for designing efficient parallel GAs, see Goldberg [76] and Cantú-Paz [79,80].

Hybridization

The central idea in hybridization is to combine two or more optimization methods

into a single hybrid technique. Typically, global–local hybrids that combine two optimization procedures are used; one of these methods is capable of effective global exploration of the search space, whereas the other is capable of quickly reaching a local optimum. In hybrid GAs, a GA would be typically used as a global optimizer and some form of hill climbing would be used as a local searcher. The local searcher may be run on every solution in the population or only on a portion of the population (e.g., on the best solution obtained). Hybrid GAs are sometimes referred to as *memetic GAs*. A survey to hybrid GAs can be found in Sinha and Goldberg [81].

One of the key issues in the design of efficient hybrid procedures is the appropriate coordination of the global and local search. The two main possibilities are captured in the literature by the terms *Baldwinian* and *Lamarckian* hybrid [82]:

Baldwinian Hybrid. In a Baldwinian hybrid, the local search procedure uses the global procedure's value as a starting point, searches until reaching an optimum, and then passes back the function value found *without* backsubstituting the solution value found.

Lamarckian Hybrid. In a Lamarckian hybrid, the local search procedure again uses the global procedure's value as a starting point, searches until reaching an optimum, and then passes back the function value found *with* backsubstitution of the solution value found.

At first sight, Lamarckian hybrids may seem more intuitive, but in some cases

backsubstitution of solution values found by local search has been found to reduce solution variance to a point such that subsequent exploration is diminished. Various rules of thumb have suggested Baldwinian moves with a small percentage of Lamarckian moves as desirable in practice [68].

Finding an adequate way to split resources between the global and local search requires a systems-level understanding of the roles of the two procedures. Goldberg and Voessner [83] proposed such a theory and Sinha and Goldberg [84], Sinha [85], and Sinha *et al.* [86] explored the theory in the context of simple GAs. Simply stated, the theory suggests that the key role of the global searcher is to find one or a number of good regions and the key role of the local searcher is to find local optima within these regions.

Evaluation Relaxation

For many optimization problems, evaluation of the objective function is computationally expensive. The number of evaluations until a solution is found can be substantially decreased using hybridization and prior knowledge, and a number of studies exist that support this fact [21,34,54,87–89]. However, to deal with computationally expensive objective functions, one may also have to use past evaluations to estimate fitness values for some of the new solutions. There are two basic approaches to using past evaluations to estimate fitness values of new solutions.

Exogenous Models. Past evaluations can be used to build a fast, approximate model of the objective function, which can be subsequently used to evaluate some of the new candidate solutions instead of the original, computationally expensive objective function [89–92]. For example, a simple linear model can be adjusted to fit the fitness values in the population of parents and then sampled to estimate fitness values of some of the new solutions [90]. More advanced models can be developed based on probabilistic models discovered by EDAs [89,91] or neural networks [92].

Endogenous Models. The fitness of new solutions can also be estimated directly from parental fitness values [93] because new solutions have often fitness values similar to the parent solutions used to create these new solutions. For example, the fitness of a new solution can be estimated as an average fitness of the parents that were used to create this new solution [93].

Using an approximate model to evaluate some candidate solutions has typically a similar effect as if the fitness function was affected by additive external noise [90]. Consequently, the overall number of candidate solutions that must be considered until an accurate solution is obtained can be expected to increase. However, since many of the solutions are evaluated using a fast approximation of the computationally expensive fitness function, the overall computational time can be reduced substantially. In practice, even speedups of over 50 can be obtained if advanced exogenous models are used in combination with model building using EDAs [91].

Time Continuation

Different variation operators have different function and effects. Recombination combines bits and pieces between pairs of promising solutions whereas mutation modifies candidate solutions to explore their immediate neighborhood. The optimal division of labor between the two operators depends on the specifics of the problem and the time available to complete the task. Furthermore, depending on the time available and problem specifics, in some situations it may be preferable to search for solutions using a large population, whereas in other cases it may be preferable to search for solutions using a small population with multiple convergence epochs. In time continuation [21,94,95], the focus is on the optimal division of labor between different search operators and other parameters of a GA with the focus on either (i) maximizing solution quality within a limited computational budget or (ii) minimizing computational time for obtaining a solution of given quality.

Theoretical results for time continuation indicate that for additively separable problems with subproblems of equal salience, multiple convergence epochs with a rather small population are expected to be more efficient. However, in the presence of noise and overlap between subproblems, a single epoch with a large population is expected to be more efficient. For an overview of work on time continuation and theoretical results, please see Srivastava and Goldberg [95] and Srivastava [96].

GUIDELINES FOR APPLYING GENETIC ALGORITHMS TO A NEW PROBLEM

One of the main advantages of GAs over other optimization methods is that it is relatively straightforward to apply GAs to new optimization problems. This section provides guidelines that can serve as a starting point for novices who want to apply a GA to a new problem.

Parameters. There are numerous parameters that must be set in order to apply a GA to a new problem. The simple GA implementation presented in the section titled “Genetic Algorithm Procedure” contains three main parameters (besides the problem-dependent ones). The best values of these three parameters depend on the problem being solved, but there are some general rules of thumb that provide a fairly good starting point.

- *Population size, N .* The population size is probably the most important parameter to tune and using populations that are too small is a frequent mistake that GA researchers and practitioners make. Generally, the population size should increase with problem size (the number of bits or variables), and the larger the population size, the better the obtained solution should be. Unless the evaluation of the objective function is prohibitively slow, the population size can range from tens to thousands or even more. As a starting point

for initial runs, the population size may be set to the problem size, $N = n$. If using $N = n$ is infeasible, one may start with smaller values of N , such as $N = 50$. Changing the population size and rerunning the GA with larger and smaller populations (e.g., $N/2$ and $2N$) provides an indication of whether the current population size is adequate. If increasing the population size leads to better solutions, the population size should be increased. If increasing the population size leads to solutions of about the same quality, the current population size is likely to suffice. Of course, if the evaluation of the objective function is computationally intensive, large populations may become intractable and, to run a sufficient number of generations, one is often forced to use a relatively small population size.

- *Crossover probability, p_c .* The probability of crossover in GAs is typically quite large. For example, DeJong and Spears [97] suggest that $p_c = 0.6$ regardless of the number of bits n . Many researchers use an even larger probability of crossover, for example, $p_c = 0.9$ or $p_c = 1$.
- *Mutation probability, p_m .* The probability of mutation is typically set so that the expected number of modified bits is fixed regardless of n and that only a few bits are expected to change on average. For example, one may use $p_m = 1/n$. Some researchers use larger values of p_m , but in many cases the reasons for increasing the probability of mutation are that the remaining parameter settings are inadequate.

Providing the GA with adequate values of parameters is a long-standing topic in GA research, and for more information, there are numerous publications that the reader may consult Goldberg [21] and Lobo *et al.* [98] provide a good starting point for these efforts.

Termination. Typically, each GA run is terminated when the number of generations reaches a predefined threshold, when a solution of sufficient quality has been achieved, or when the GA run starts to stagnate without improving the quality of the population for a given number of iterations. One of the frequent mistakes of GA practitioners is to underestimate the population size and then overestimate the number of generations. This can lead to an unnecessary increase in computational requirements of the GA by executing a large number of GA iterations with no or only little improvement. The number of generations is typically only several times larger than the number of bits in the problem. One way to avoid setting a strict upper bound on the number of generations is to terminate the run when the average fitness of the current population does not improve much for a given number of iterations (e.g., 5 or 10 generations). Of course, the best way to terminate a GA run depends on the problem being solved and several trial runs should provide enough input to make an informed decision.

Representation. Representation of candidate solutions is a critical component of a GA. One may either use the original representation of candidate solutions or one may map the original representation into binary strings, real-valued vectors, or another representation. A good starting point is to use the original representation for the particular problem with no significant modifications or transformations. In the initial stage, modifications should be done only if the chosen implementation necessitates them. If the results obtained are not satisfactory, alternative representations should be examined.

Operators. Numerous operators were described in this article and more can be found in the references provided. What operators should one choose? The best way to start, similarly as for the representations, is to try simple

operators provided in the literature for the representation used. If one starts with a computer implementation of a GA downloaded from the Internet, the implementation most likely includes numerous operators to consider; sticking with the default choices should be a great way to start. If the results are not satisfactory, different operators may be examined and specialized operators may be designed.

Fitness Function. The fitness function resides right at the heart of a GA—the fitness function defines what solutions are good and what solutions are bad. Since the fitness function depends completely on the problem being solved, it is difficult to give a set of general guidelines for designing adequate fitness functions. It is important to keep in mind that the GA does not know what your original problem is; instead, the GA tries to maximize the fitness function over the space of admissible solutions defined by the representation used. The best way to start in the design of a fitness function is to look at the examples from the specific area.

STARTING POINTS FOR OBTAINING ADDITIONAL INFORMATION

Introductory Books and Tutorials

Numerous books and other publications exist that provide introduction to GAs and additional starting points. The following list of references provides some of them: [1,2,24,31,99–105].

Software

The following list provides some of the popular GA implementations available online free of charge. These implementations should provide a good starting point for the interested reader.

- *A C++ Library of Genetic Algorithm Components*
<http://lancet.mit.edu/ga/>

- *Algorithm::Evolutionary, Perl Library for Evolutionary Computation*
<http://opeak.sourceforge.net/>
- *Genetic ALgorithm Optimized for Portability and Parallelism System (GALLOPS)*
<http://garage.cse.msu.edu/software/gallops/index.html>
- *Open BEAGLE, a Versatile Evolutionary Computation Framework*
<http://beagle.gel.ulaval.ca/>
- *Simple GA Implementation in C (based on Goldberg [2])*
<http://www.illigal.uiuc.edu/pub/src/simpleGA/C/>
- *Other GA Software Packages*
<http://www-2.cs.cmu.edu/afs/cs/project/ai-repository/ai/areas/genetic/ga/systems/0.html>

Journals

The following journals are key venues for papers on GAs and evolutionary computation, although papers on GAs can be found in many other journals focusing on optimization, artificial intelligence, machine learning, and applications.

- *Evolutionary Computation* (MIT Press)
<http://www.mitpressjournals.org/loi/>
- *Evolutionary Intelligence* (Springer)
<http://www.springer.com/engineering/journal/12065>
- *Genetic Programming and Evolvable Machines* (Springer)
<http://www.springer.com/computer/ai/journal/10710>
- *IEEE Transactions on Evolutionary Computation* (IEEE Press)
<http://ieeexplore.ieee.org/servlet/opac?punumber=4235>
- *Natural Computing* (Springer)
<http://www.springer.com/computer/theoretical+computer+science/journal/11047>

Conferences

The following conferences provide the most important venues for publishing papers on

GAs and evolutionary computation, although similarly as for journals, papers on GAs are often published in other venues.

- *ACM SIGEVO Genetic and Evolutionary Computation Conference (GECCO)*
- *European Workshops on Applications of Evolutionary Computation (EvoWorkshops)*
- *IEEE Congress on Evolutionary Computation (CEC)*
- *Main European Events on Evolutionary Computation (EvoStar)*
- *Parallel Problem Solving in Nature (PPSN)*
- *Simulated Evolution and Learning (SEAL)*.

GEOMETRIC PROGRAMMING

JAYANT RAJGOPAL

Department of Industrial Engineering,
University of Pittsburgh, Pittsburgh,
Pennsylvania

Geometric programming (GP) is a methodology for solving algebraic nonlinear optimization problems that possess a specific structure. In this article, we present a very brief historical context for GP, followed by principal results for the original GP problem, various subsequent generalizations, and an overview of computational issues and solution algorithms.

HISTORICAL CONTEXT

The original GP formulation and much of the supporting theory were developed between 1961 and 1967. The initial motivation was provided by the physicist Clarence Zener, who was the director of Westinghouse Electric Corporation Research Labs in Pittsburgh. While looking for more efficient ways to solve engineering design problems that were of interest to Westinghouse, Zener published two papers in 1961–1962 [1,2] where he showed that problems with a certain structure could be solved very simply but elegantly, and that the solution also had invariance properties that were interesting from an engineering perspective. Coincidentally, during the same time period Richard Duffin, a mathematician at Carnegie Institute of Technology (now Carnegie Mellon University) in Pittsburgh, was working on a duality theory with applications to nonlinear programming (NLP). On learning of each other's work, the two began a collaborative effort to ground Zener's technique with the proper mathematical foundation, resulting in the formal birth of GP. Subsequently, Elmor Peterson, a doctoral student of Duffin at the time, worked on formulating and developing the theory for constrained problems.

Possibly the most important feature of GP is that a problem with highly nonlinear constraints can be stated equivalently in the dual form with only linear constraints; this is obviously very desirable when developing solution procedures. A second important feature of GP is that it yields invariance properties with very useful practical implications. For example, in some cases for a given set of design constraints the different cost components of an optimal design must make the same *relative* contributions to total cost, regardless of the individual cost coefficients for the components. These invariance properties are especially significant in engineering design.

The joint efforts of Duffin *et al.* culminated in the publication of the seminal text in this area [3] in 1967. Since then, GP's attractive structural properties and its elegant theoretical basis have led to the development of a number of algorithms for solving GP problems, several extensions of the original formulation to more general forms, and a wide and eclectic range of applications. It is now a mature area and many texts on NLP cover the subject in varying degrees of detail. Books and collected volumes specifically focused on GP include Duffin *et al.* [3], Zener [4], Beightler and Phillips [5], Avriel [6], Cao [7], Chiang [8].

POSYNOMIAL GEOMETRIC PROGRAMMING

In this section we present the original version of GP, along with its duality theory.

The Primal-Dual Pair in GP

The primal geometric program may be stated as follows:

Program P

$$\text{Minimize } g_0(\mathbf{t}) \quad (1)$$

$$\text{s.t. } g_k(\mathbf{t}) \leq 1, \quad k = 1, 2, \dots, p, \quad (2)$$

$$\mathbf{t} \in \mathbf{R}_{++}^m,$$

$$\begin{aligned} \text{where } g_k(\mathbf{t}) &= \sum_{i \in [k]} c_i \prod_{j=1}^m t_j^{a_{ij}}, \\ k &= 0, 1, \dots, p; \quad c_i \in \mathbf{R}_{++} \forall i, \\ a_{ij} &\in \mathbf{R} \forall i, j. \end{aligned} \quad (3)$$

Each function $g_k (k = 0, 1, \dots, p)$ is a *generalized* polynomial consisting of a sum of terms, where each term within the polynomial has a strictly positive coefficient followed by a product of the design variables, with each raised to an exponent. Unlike a standard polynomial, these exponents are not restricted to the set of nonnegative integers but may take on any real value (including negative values). These generalized polynomials with positive coefficients are referred to as *posynomials*. The domain of a posynomial is thus necessarily restricted to the set of strictly positive real numbers. There are a total of n terms included in the $p + 1$ posynomials, and the index set $I = [1, 2, \dots, n]$ is used to number these sequentially so that the first term of posynomial 0 has the index 1 and the last term of posynomial p has the index n . The index subset $[k]$ numbers the terms in the k th posynomial, with $I = [0] \cup [1] \cup \dots \cup [p]$ and $[k] \cap [l] = \emptyset$ for $k \neq l$. The inputs to the problem are (i) the (positive) coefficient vectors $\mathbf{c}^k, k = 0, 1, \dots, p$ and (ii) the $n \times m$ exponent matrix $\mathbf{A}$, where the entry in row i and column $j (= a_{ij})$, is the exponent for variable t_j in term i . As an illustrative example consider the following formulation [5]:

$$\begin{aligned} \text{Minimize } & t_1^{-1} t_2^{-1} t_3 + 25 t_1 t_2^{-1} \\ \text{s.t. } & t_1 t_2 \leq 1 \\ & 5 t_1 t_3^{-1} + t_2 t_3^{-1} \leq 1; \quad t_1, t_2, t_3 > 0 \end{aligned}$$

Here $m = 3; n = 5; p = 2; [0] = \{1, 2\}, [1] = \{3\}, [2] = \{3, 4\}$, with $I = [0] \cup [1] \cup [2] = \{1, 2, 3, 4, 5\}$

$$\mathbf{c} = \begin{bmatrix} 1 \\ 25 \\ 1 \\ 5 \\ 1 \end{bmatrix} \text{ and } \mathbf{A} = \begin{bmatrix} -1 & -1 & 0 \\ 1 & -1 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \end{bmatrix}.$$

The dual corresponding to Program P may be stated as

Program D

$$\text{Maximize } v(\boldsymbol{\lambda}, \boldsymbol{\delta}) = \left(\prod_{i=1}^n \left(\frac{c_i}{\delta_i} \right)^{\delta_i} \right) \left(\prod_{k=0}^p \lambda_k^{\lambda_k} \right) \quad (4)$$

$$\text{s.t. } \sum_{i \in [k]} \delta_i = \lambda_k, \quad k = 1, 2, \dots, p, \quad (5)$$

$$\sum_{i \in [0]} \delta_i = \lambda_0 = 1, \quad (6)$$

$$\sum_{i=1}^n \delta_i a_{ij} = 0, \quad j = 0, 1, \dots, m, \quad (7)$$

$$\begin{aligned} \delta_i, \lambda_k &\geq 0 \text{ for } i \in I \text{ and} \\ k &= 1, 2, \dots, p. \end{aligned}$$

The constraint specified by Equation (6) is referred to as the *normality* condition and those specified in Equation (7) are referred to as the *orthogonality* conditions; the dual vector $\boldsymbol{\delta}$ must be orthogonal to each column of $\mathbf{A}$. It is also shown in Duffin *et al.* [3] that λ_k for $k \geq 1$ is equivalent to the Lagrange multiplier for constraint k . Note that effectively there are n variables (one δ_i corresponding to each term in the primal) and $(m + 1)$ constraints, since the vector $\boldsymbol{\lambda}$ could be eliminated by substituting $\lambda_k = \sum_{i \in [k]} \delta_i$ for all k . Also note that while the term $(c_i/\delta_i)^{\delta_i}$ is undefined if $\delta_i = 0$, we define this to be 1, since this quantity goes to 1 in the limit as $\delta_i \rightarrow 0^+$. The earlier example yields

$$\begin{aligned} \text{Maximize } v(\boldsymbol{\lambda}, \boldsymbol{\delta}) &= \left(\frac{1}{\delta_1} \right)^{\delta_1} \left(\frac{25}{\delta_2} \right)^{\delta_2} \left(\frac{1}{\delta_3} \right)^{\delta_3} \\ &\quad \left(\frac{5}{\delta_4} \right)^{\delta_4} \left(\frac{1}{\delta_5} \right)^{\delta_5} (\lambda_0)^{\lambda_0} (\lambda_1)^{\lambda_1} (\lambda_2)^{\lambda_2} \\ \text{s.t. } &\delta_1 + \delta_2 = \lambda_0; \delta_3 = \lambda_1; \delta_4 + \delta_5 = \lambda_2; \\ &\lambda_0 = 1 \\ &-\delta_1 + \delta_2 + \delta_3 + \delta_4 = 0; \\ &-\delta_1 - \delta_2 + \delta_3 + \delta_5 = 0; \\ &-\delta_4 - \delta_5 = 0; \\ &\boldsymbol{\lambda} \geq \mathbf{0}, \boldsymbol{\delta} \geq \mathbf{0}. \end{aligned}$$

Next, we present a transformation that yields an attractive result for the primal. Suppose we define $z_j = \ln t_j$, so that $t_j = e^{z_j}$. We obtain the *transformed* primal, which is stated as follows:

Program P_z

$$\text{Minimize } g_0(\mathbf{z}) \quad (8)$$

$$\text{st } g_k(\mathbf{z}) \leq 1, k = 1, 2, \dots, p, \quad (9)$$

$$\mathbf{z} \in \mathbb{R}^m,$$

$$\begin{aligned} \text{where } g_k(\mathbf{z}) &= \sum_{i \in [k]} c_i e^{\sum_{j=1}^m a_{ij} z_j} \\ &= \sum_{i \in [k]} e^{\chi_i + \sum_{j=1}^m a_{ij} z_j}, \\ k &= 0, 1, \dots, p, c_i > 0. \end{aligned} \quad (10)$$

Note that we define $\chi_i = \ln c_i$ and that the transformed functions $g_k(\mathbf{z})$ are all positive exponential functions. To examine some of the results that follow from P_z , let us define

$$x_i = \sum_{j=1}^m a_{ij} z_j, \quad i \in I. \quad (11)$$

Thus the vector $\mathbf{x} \in \mathbb{R}^n$ is restricted to lie in the column space of the exponent matrix $\mathbf{A}$. Now consider the equivalent problem of minimizing $\sum_{i \in [0]} c_i e^{x_i}$, st $\sum_{i \in [k]} c_i e^{x_i} \leq 1, k = 1, 2, \dots, p$. If the rank of $\mathbf{A}$ is less than m , then there is some partition of its column vectors into a basis with linearly independent vectors and another set with the remaining columns, each of which is linearly dependent on the columns in the basis. The variables z_j corresponding to the columns in the latter set can then be assigned arbitrary values without having any effect on the minimum value of P_z ; thus they can essentially be eliminated from the problem along with their columns in $\mathbf{A}$. Thus, the rank of $\mathbf{A}$ is at least m . Now suppose $m = n$ (so that $\mathbf{A}$ is square with full rank). Consider a vector $\mathbf{M} \in \mathbb{R}^n$ with every element equal to $-M$, where M is some arbitrarily large value. We can always find $\mathbf{z} \neq \mathbf{0}$ such that $\mathbf{A}\mathbf{z} = \mathbf{M}$, that is, such that $\sum_{j=1}^m a_{ij} z_j = -M$ for every i . It follows from Equation (10) that each $g_k(\mathbf{z})$ can then be made arbitrarily close to zero, and thus P_z

reduces to the trivial case where it is feasible but has an infimum of 0 that is never attained. These observations lead to the following proposition.

Proposition 1. *Every nontrivial GP problem can be formulated so that (i) the exponent matrix has rank m , and (ii) $m < n$.*

The nonnegative quantity $D = n - (m + 1)$ is referred to as the *degree of difficulty* of the GP problem; the term is related to how underdetermined the dual constraints system ((6) and (7)) is. For our earlier example, $D = 1$. Another important result that follows from the above transformation is the following theorem, the proof for which may be found in Duffin *et al.* [3].

Theorem 1. *Program P_z is a convex program.*

Note that not all posynomials are convex, so that not all primal problems in the format of Program P are convex programs; however, they can all be restated as convex programs using the above transformation.

Duality Theory for GP

We now present (without detailed proofs) the main duality theorems for posynomial GP. The proofs hinge on a generalization of the classical inequality relating the arithmetic and geometric means of a set of numbers (the former is at least as large as the latter), and make use of the standard Lagrange multiplier approach. The interested reader is referred to Duffin *et al.* [3] for details. For the sake of notational convenience, we assume that the λ_k variables in the dual formulation have been eliminated by substituting $\lambda_k = \sum_{i \in [k]} \delta_i$ for all k , and thus, we use $v(\lambda, \delta)$ and $v(\delta)$ interchangeably.

Theorem 2. *Suppose $\mathbf{t} \in \mathbb{R}^m$ is feasible in the primal (Program P), and the vector $\delta \in \mathbb{R}^n$ is feasible in the dual (Program D). Then $g_0(\mathbf{t}) \geq v(\delta)$.*

Thus, any solution to the linear system represented by the dual constraints readily generates a lower bound on the primal

optimum using the above “weak” duality theorem. Next, we state conditions that guarantee the existence of feasible vectors and a stronger duality result. Before doing so we make the following definition.

Definition 1. Program P is said to be superconsistent if there is at least one vector $\mathbf{t} \in \mathbf{R}_{++}^m$ such that $g_k(\mathbf{t}) < 1, k = 1, 2, \dots, p$.

Theorem 3. Suppose (i) Program P is superconsistent and (ii) the primal objective $g_0(\mathbf{t})$ attains its constrained minimum at a point $\mathbf{t}^*$ feasible in P . Then Program D is consistent and the dual objective $v(\delta)$ attains its constrained maximum at a point (δ^*) feasible in D . Moreover,

$$1. \quad g_0(\mathbf{t}^*) = v(\delta^*) \quad (12)$$

$$2. \quad \delta_i^* = \begin{cases} \frac{c_i \prod_{j=1}^m (t_j^*)^{a_{ij}}}{g_0(\mathbf{t}^*)} = \frac{c_i \prod_{j=1}^m (t_j^*)^{a_{ij}}}{v(\delta^*)}, i \in [0] \\ \lambda_k^* \left(c_i \prod_{j=1}^m (t_j^*)^{a_{ij}} \right), i \in [k], \\ k = 1, 2, \dots, p \end{cases} \quad (13)$$

The above “strong” duality theorem also provides via Equation (13) a relationship between the optimal values of the primal and dual variables. Note that superconsistency is like a regularity condition in general NLP and the other assumption eliminates pathological cases where the GP might have an infimum that is not attained. The following theorem specifies conditions under which this latter assumption holds.

Theorem 4. If Program P is consistent and there exists $\delta \in \mathbf{R}_{++}^n$ that is feasible in Program D , then the objective for Program P attains its constrained minimum at a feasible point.

While the duality results just presented are adequate for most practical situations, they are not comprehensive because of requirements such as superconsistency and the attainment of minima/maxima. We

conclude this section with a discussion of the so-called *refined* duality theory of GP, which dispenses with these requirements. Since the results from this are primarily of theoretical interest, our discussion is very brief.

We now generalize the problem so that the primal objective is to find the constrained *infimum* of $g_0(\mathbf{t})$, while the dual objective is to find the constrained *supremum* of $v(\lambda, \delta)$. Much of the refined duality theory is based on determining if for each value of $i = 1, 2, \dots, n$ there is at least one vector $\delta \in \mathbf{R}_+^m$ that satisfies the orthogonality constraints (7) and also has $\delta_i > 0$. The set of all i for which this is true determines the so-called *irreducible integer set* (Γ). If Γ is identical to the original index set I , the corresponding primal–dual pair is said to be *canonical*; otherwise it is said to be *degenerate*, and if $\Gamma \cap [0] = \emptyset$ then it is said to be *totally degenerate*. Essentially, canonical programs may be viewed as well-behaved with strong results similar to those presented earlier in this section, while totally degenerate programs represent the other end of the spectrum with inconsistent duals and a primal infimum of zero even when the primal is consistent. Degenerate programs that are not totally degenerate lie in between; they can be reduced to canonical form by essentially deleting those terms that do not belong to Γ . For more details on these concepts as well as other results, the interested reader is referred to Duffin *et al.* [3] or Rajgopal [9].

EXTENSIONS OF GEOMETRIC PROGRAMMING

Typically, the term *generalized geometric programming* (GGP) is used to describe extensions of the original (posynomial) GP formulation to more general forms. However, there appears to be a fair amount of ambiguity in terms of what exactly this term encompasses. For example, Beightler and Phillips [5] describe a GGP as one where the coefficient c_i in term i does not have to be strictly positive, and where the directions of the inequalities in the constraints could be reversed; this latter situation, in particular, is referred to as *reversed geometric programming*, and the class of problems just described

is more generally referred to by the term *signomial geometric programming (SGP)*. The initial work in this area was done by Passy and Wilde [10]. On the other hand, Peterson [11,12] uses the term GGP to describe a more general class of separable problems with an underlying algebraic structure that is linear or for which linearity can be induced. He then derives general duality and optimality results for this class of problems based mainly on conjugate transforms [13]. More recently, Boyd *et al.* [14] and Chiang [8] describe a GGP as a program in which the objective and constraint functions are *generalized posynomials*. The latter term is used to describe any function that can be formed from posynomials using the operations of addition, multiplication, (positive) exponentiation, and maximum. Such functions have the advantage of maintaining convexity.

We take a neutral view and simply use this section to consider various extensions to the original (posynomial) GP formulation that have been discussed in the literature. While these extensions encompass a much broader class of algebraic nonlinear optimization problems, convexity is unfortunately not guaranteed any longer in many cases, and thus the duality results for these are not as elegant. Nevertheless, several of these extensions have been well studied (especially from a computational perspective) since they capture many practical problems.

Signomial GP (SGP)

The first extension uses signomial functions. These are posynomials where each term is multiplied by a *signum* factor of ± 1 . Moreover, to account for reversed constraints the RHS of each constraint could now be 1 or -1. The primal may be stated as follows:

Program SP

Minimize $g_0(\mathbf{t})$

$$\text{st } g_k(\mathbf{t}) \leq \sigma_{k0}, \quad k = 1, 2, \dots, p, \quad (14)$$

$$\mathbf{t} \in \mathbf{R}_{++}^m,$$

$$\text{where } g_k(\mathbf{t}) = \sum_{i \in [k]} \sigma_i c_i \prod_{j=1}^m t_j^{a_{ij}},$$

$$k = 0, 1, \dots, p, c_i > 0, \quad (15)$$

$$\text{and } \sigma_{k0} = \pm 1, k = 1, 2, \dots, p;$$

$$\sigma_i = \pm 1, i = 1, 2, \dots, n.$$

The formulation is almost identical to Program P , with the exception of the signum factors σ_i and σ_{k0} that capture the sign of the coefficient for term i and the RHS of constraint k respectively; note that these are *given* as part of the problem formulation. This also allows for a much more generalized constraint structure including “ $\geq$ ” and equality constraints. To construct the dual of this problem one needs to introduce a new signum factor σ_{00} , which represents the sign of the primal objective at the optimum. This is not known *a priori* but for many practical problem formulations it can be guessed intelligently, and in engineering applications it is positive in the vast majority of cases. In the worst case, a wrong guess can be discovered during the course of the dual computations.

Program SD

$$\begin{aligned} \text{Maximize } v(\lambda, \delta) = & \sigma_{00} \left(\prod_{i=1}^n \left(\frac{c_i}{\delta_i} \right)^{\delta_i \sigma_i} \right. \\ & \left. \times \prod_{k=1}^p \lambda_k^{\lambda_k \sigma_{k0}} \right)^{\sigma_{00}} \end{aligned} \quad (16)$$

$$\text{s.t. } \sigma_{k0} \sum_{i \in [k]} \sigma_i \delta_i = \lambda_k, \quad k = 1, 2, \dots, p, \quad (17)$$

$$\sigma_{00} \sum_{i \in [0]} \sigma_i \delta_i = 1, \quad (18)$$

$$\sum_{i=1}^n \sigma_i \delta_i a_{ij} = 0, \quad j = 0, 1, \dots, m, \quad (19)$$

$$\delta_i, \lambda_k \geq 0 \text{ for } i \in I \text{ and}$$

$$k = 1, 2, \dots, p.$$

The constraints given by Equations (18) and (19) are referred to as *generalized normality* and *generalized orthogonality* conditions, respectively. Unlike the dual program in the section titled “Duality Theory for GP,” this

Program SD does not in general yield any strong duality results and since Program SP cannot be reformulated as a convex program, there will in general, be a duality gap. Thus this dual is not particularly useful since duality results for this pair are not as strong as the ones in the section titled “Duality Theory for GP,” and as a result, they also have limited use from an algorithmic/computational perspective. For more discussion on special cases of the SGP problem the reader is referred to Beightler and Phillips [5].

Transcendental Geometric Programs (TGP)

Introduced by Lidor and Wilde [15], this extension to GP allows some of the variables (referred to as *transcendental variables*) to also appear as exponents or logarithms in the primal geometric program, resulting in the so-called posynomial functions. Suppose that in addition to the usual m “algebraic” variables $t_1, t_2, \dots, t_m$, we have q such transcendental variables; as a matter of notational convenience we denote these via $s_1, s_2, \dots, s_q$. Then the primal transcendental geometric programming (TGP) is defined as

Program TGP

$$\text{Minimize } g_0(\mathbf{t}, \mathbf{s}) \quad (20)$$

$$\text{st } g_k(\mathbf{t}, \mathbf{s}) \leq 1, \quad k = 1, 2, \dots, p, \quad (21)$$

$$\mathbf{t} \in \mathbf{R}_{++}^m, \mathbf{s} \in \mathbf{R}_{++}^q,$$

$$\begin{aligned} \text{where } g_k(\mathbf{t}, \mathbf{s}) = & \sum_{i \in [k]} c_i \left(\prod_{j=1}^m t_j^{a_{ij}} \right) \\ & \times \left(\prod_{l=1}^q s_l^{b_{il}} \exp(d_{il} s_l) \right), \\ & k = 0, 1, \dots, p; \end{aligned} \quad (22)$$

$$\text{and } c_i \in \mathbf{R}_{++} \forall i;$$

$$a_{ij}, b_{il}, d_{il} \in \mathbf{R} \forall i, j, l, c_i > 0.$$

Note that if either (i) $d_{il} = 0$ for all i and l , or (ii) $b_{il} = 0$ for all i and l , we have a regular GP in $m + l$ variables (in case (ii) we can define $s'_l = \exp(s_l)$ to obtain the necessary form). An example of a function that leads to a transcendental program is where each term in

the summation in Equation (22) is a logarithmic function of the form $c_i \prod_{j=1}^m x_j^{a_{ij}} (\log x_j)^{b_{ij}}$; here we get the necessary form by defining $s_j = \log x_j$. Unfortunately, because of the lack of convexity Program TGP could have several local minima and even though a dual can be derived for it, the latter is not very useful in that it does not provide a lower bound on the optimum value of the primal. However, if we *fix* the transcendental variables, conditions can be specified whereby the primal–dual pair reduces to the traditional GP primal–dual pair. For more details and other interesting properties, the interested reader is referred to Lidor and Wilde [15].

Quadratic Posylognomials (QPL)

These functions were introduced and analyzed as extensions to GP by Hough and Goforth [16]. To understand the motivation, consider a term in a posynomial: $u = c \prod_j t_j^{a_j}$. This may be rewritten as $\ln u = \ln c + \sum_j a_j \ln t_j$, that is, as a linear function of the logarithm of the design variables. This type of log-linear relationship has long been known in many engineering and scientific contexts; this was even pointed out by Zener during the original development of GP. However, it has been postulated that in some cases (e.g., the machining economics problem with Taylor’s tool life equation) a quadratic—rather than a linear—logarithmic relationship of the following form is more appropriate:

$$\ln u = \ln c + \sum_{j=1}^m a_j \ln t_j + \frac{1}{2} \sum_{j=1}^m \sum_{l=1}^m b_{jl} \ln t_j \ln t_l. \quad (23)$$

Upon exponentiation this leads to the form

$$\begin{aligned} u &= c \prod_{j=1}^m t_j^{a_j} \cdot \prod_{j=1}^m t_j^{\frac{1}{2} \sum_{l=1}^m b_{jl} \ln t_l} \\ &= c \prod_{j=1}^m t_j^{a_j + \frac{1}{2} \sum_{l=1}^m b_{jl} \ln t_l}. \end{aligned} \quad (24)$$

Hough and Goforth define a *quadratic posylognomial (QPL)* as any finite sum of terms such as those in Equation (24) and

regular posynomial terms, and attempted to develop extensions of traditional GP theory to programs involving such functions. However, there is no way to reduce these programs to the GP form so that, once again, the results are not as clean or as powerful as in traditional GP.

Quadratic Geometric Programming (QGP)

Consider the symmetric $m \times m$ matrix $\mathbf{B} = [b_{jl}]$ of quadratic term multipliers in Equation (23). It can be shown that if $\mathbf{B}$ is positive semidefinite, then each term as given by Equation (24) is convex, and hence the entire quadratic posylognomial is convex in $\mathbf{z} = \ln \mathbf{t}$. Under such conditions the QPL formulation of the previous section reduces to a convex program in the logarithm of the original design variables, similar to Program P_z in the section titled “The Primal–Dual Pair in GP.” Now consider the functions $g_k(\mathbf{z})$ given by Equation (10) that were used to define Program P_z . Jefferson and Scott [17] redefine this by appending to the linear function, a quadratic term that is defined by a symmetric positive definite matrix $\mathbf{B}$:

$$g_k(\mathbf{z}) = \sum_{i \in [k]} \exp(\chi_i + \mathbf{a}^i \mathbf{z} + \mathbf{z}^T \mathbf{B} \mathbf{z}); \quad k = 0, 1, \dots, p. \quad (25)$$

As before, we define $\chi_i = \ln c_i$, and $\mathbf{a}^i$ is a row vector of size m representing the i th row of the original exponent matrix $\mathbf{A}$. They then define a quadratic geometric programming (QGP) as follows:

Program QGP

$$\text{Minimize } g_0(\mathbf{z}) \quad (26)$$

$$\text{s.t. } g_k(\mathbf{z}) \leq 1, k = 1, 2, \dots, p, \quad (27)$$

$$\mathbf{z} \in \mathbf{R}^m,$$

where $g_k(\mathbf{z}), k = 0, 1, \dots, p$ is given by Equation (25), and can be shown to be convex in $\mathbf{z}$.

Composite Geometric Programming (CGP)

Finally, we describe a further generalization of Program QGP described in the previous

section; this was formalized by Jefferson *et al.* [18]. Consider Equation (25) once again, but with the quadratic form in the exponentiation of each term replaced with some *general* convex function:

$$g_k(\mathbf{z}) = \sum_{i \in [k]} \exp(\chi_i + \mathbf{a}^i \mathbf{z} + h_i(\mathbf{z})); \quad k = 0, 1, \dots, p. \quad (28)$$

The optimization problem in composite geometric programming (CGP) is the same as the one described in Equations (26) and (27), but with $g_k(\mathbf{z})$ now described via Equation (28). Since each function in Equation (28) is still convex, it is clear that CGP is also a convex program but is more general than QGP.

COMPUTATIONAL ISSUES AND ALGORITHMS

While posynomial GPs are convex programs and traditional NLP methods can be applied to solve these, the special structure of the primal and (especially) the dual program, and the relationships between the optimum solutions to the two have led to the development of a number of computational algorithms designed specifically for geometric programs. It is not particularly surprising that such algorithms are more robust and also tend to perform better; indeed, a computational study done by Dembo [19] confirmed this fact. These structures are examined further in the section titled “Posynomial Structure and Primal–Dual Relationships at the Optimum.”

Broadly speaking, algorithms for GP may be classified into two categories: posynomial GP methods and signomial GP methods. Solution techniques for posynomial programs may be categorized as either primal-based algorithms that directly solve the original, completely nonlinear problem, or dual-based algorithms that solve the equivalent linearly constrained dual. There are two schools of thought on which approach is superior, and in order to understand the pros and cons of each it is worth examining the structure of the dual problem given by expressions (4–7) in the section titled “The Primal–Dual Pair in GP.”

Posynomial Structure and Primal–Dual Relationships at the Optimum

First, note that the dual has a nonlinear objective but is linearly constrained. Second, since the log function is monotone increasing in its argument one could choose to replace the dual objective with its logarithm and maximize the latter instead. There are some advantages in doing so. If the λ_k are eliminated by substituting from Equations (5) and (6) into Equation (4), the resulting log-dual objective is a concave function to be maximized over a polyhedral set, which is a well-studied convex program for the solution of which numerous efficient algorithms have been developed. Alternatively, if one were to retain the λ_k and work with the log-dual objective, the resulting function—although no longer concave over its domain—is separable in the δ_i and λ_k variables. Again, this is a structural feature that is attractive from a computational perspective.

Unfortunately, there are also certain disadvantages associated with dual-based methods. These problems arise when one or more primal constraints are inactive at the optimum. First, if primal constraint k is inactive at the optimum, then λ_k is equal to zero at the dual optimum. As noted in the section titled “The Primal–Dual Pair in GP” λ_k is equivalent to the Lagrange multiplier for constraint k , so that this result follows from the complementary slackness property. Then Equation (5) and nonnegativity imply that each $\delta_i, i \in [k]$ must also be equal to zero. This causes several difficulties from a computational standpoint. First, terms such as $(c_i/\delta_i)^{\delta_i}$ and $\lambda_k^{\lambda_k}$ (or $\delta_i \ln \delta_i$ and $\lambda_k \ln \lambda_k$ if the logarithm of the dual objective is being used) are now undefined. However, in the limit these quantities approach 1 (or 0 with the log-dual objective) and may therefore be explicitly defined as being equal to 1 (or 0) when δ_i and λ_k are zero; in a computer code special provisions need to be made for this. Typically, this is done by forcing the entire “block” of δ_i values to zero when several of them fall below some small tolerance. Yet another problem is that the objective function is also nondifferentiable now; this causes difficulties for any algorithm that requires the computation of gradients. To overcome these

problems, several procedures have been proposed in the literature. Unfortunately, all of them call for some relatively arbitrary rule to decide on how to address points where the dual variables approach zero. There is always some degree of ambiguity in their implementation (e.g., what is meant by “close” to zero?), and very small tolerances can often lead to numerical problems.

A second (albeit, less common) problem with slack primal constraints lies in the recovery of the primal solution vector ($\mathbf{t}$) from the optimal dual solution vector (λ, δ). With slack constraints at the optimum, there may occasionally be insufficient information to recover the primal solution vector. In order to see this, recall the system of equations representing the relationship between the primal and dual solutions at their respective optima as given by Equation (13) as part of Theorem 3. Typically, we take logarithms on both sides and obtain a system that is linear in the logarithm of t_i and can thus be easily solved to recover the optimal primal vector from the optimal dual one. However, if constraint k is inactive, then λ_k and $\delta_i, i \in [k]$ are all equal to zero, so that the equations in Equation (13) deriving from terms in k are of no use in that they provide no information! It might thus happen that when we consider all the useful equations, that is, corresponding to each term in the objective, and to each term from a constraint for which the corresponding value of λ_k is strictly *positive* at the dual optimum, we might have a system that is underdetermined and therefore impossible to solve for the optimal value of $\mathbf{t}$.

In such situations, one must resort to solving what are referred to as *subsidiary problems* in order to recover the primal vector $\mathbf{t}^*$. In fact, it might actually be necessary to solve a *sequence* of several subsidiary problems in order to obtain a primal solution. Each subsidiary problem is a separate GP problem and has the role of activating one constraint, so that the values of the dual variables corresponding to terms in the constraint are no longer zero and thus additional information becomes available in the form of Equation (13) for recovering the values of the primal variables. It was shown by

Duffin *et al.* [3] that as constraints are activated one by one and additional information becomes available, eventually one will have sufficient information to recover a complete primal solution. A further discussion of subsidiary problems is provided by Rajgopal and Bricker [20]. General issues on dual to primal conversion in posynomial GP are also discussed in detail by Dembo [21].

In summary, while the dual is more attractive on account of its structure, it also presents numerous computational problems in the presence of slack primal constraints at the optimum. This has caused some researchers to abandon the linear structure and address the primal directly, where of course, one has to contend with a highly non-linear problem. Nevertheless, the primal has several characteristics that are conducive to good algorithms [19]. Derivatives of any order for the objective and constraints are always available and relatively inexpensive to compute once the value of the posynomial is known. Also, if the problem is restated as Program P_z (Eqs (8)–(10)), we have a convex program for which very good algorithms exist. One important issue to account for is the fact that strict positivity of the decision variables could lead to a noncompact feasible set and special provisions must be made to ensure that no variable goes to zero.

Algorithms

During the first 10 or so years after its inception, a number of new algorithms were developed specifically for GP. Since then the development has been somewhat slower, although new techniques continue to appear in the literature every now and then. While general-purpose algorithms for NLP can of course be applied to GP, algorithms developed specifically around the GP structure perform better [19]. Other articles that summarize and compare various computational strategies and algorithms include Dinkel *et al.* [22], Dinkel *et al.* [23], Rijckaert and Martens [24], and Sarma *et al.* [25].

We now provide a brief overview of some of the approaches used. Many good algorithms employed a procedure called *condensation*

[26,27]. In this approach, a posynomial $g(\mathbf{t})$ is approximated by a monomial (a posynomial with one term) that is denoted by $g(\mathbf{t}, \tilde{\mathbf{t}})$ and is formed at some fixed $\tilde{\mathbf{t}} > \mathbf{0}$. Let us denote the i th term of the posynomial by $u_i = c_i \prod_{j=1}^m t_j^{a_{ij}}$ and define $\varepsilon_i(\tilde{\mathbf{t}}) = u_i/g(\tilde{\mathbf{t}})$; clearly ε_i are non-negative and sum to 1. Then the condensation at the point $\tilde{\mathbf{t}}$ is given by

$$g(\mathbf{t}, \tilde{\mathbf{t}}) = c(\tilde{\mathbf{t}}) \prod_{j=1}^m (t_j)^{a_j(\tilde{\mathbf{t}})}, \quad (29)$$

where

$$a_j(\tilde{\mathbf{t}}) = \sum_i \varepsilon_i(\tilde{\mathbf{t}}) a_{ij} \quad \text{and} \\ c(\tilde{\mathbf{t}}) = \prod_i \left(\frac{c_i}{\varepsilon_i(\tilde{\mathbf{t}})} \right)^{\varepsilon_i(\tilde{\mathbf{t}})}. \quad (30)$$

It is easily shown that the condensation is equal to the original posynomial at the point of condensation, and as a result of the arithmetic-geometric mean inequality, any point that is feasible in the original constraint using this posynomial is also feasible for the condensation. Thus condensation provides us with an outer approximation of the feasible region. This leads to the natural idea of a cutting plane because it also allows us to linearize the problem: we can take the logarithm of $g(\mathbf{t}, \tilde{\mathbf{t}})$ and obtain a linear function in the log of the design variables.

Looking at the primal problem, Rijckaert and Martens [28] took the route of iteratively solving the Kuhn–Tucker optimality conditions using condensation and a Newton–Raphson type approach. Another algorithm that deals directly with the primal and also uses condensation with a cutting plane approach was developed by Dembo [29] and is still considered one of the better algorithms for GP. Dembo also showed how this could be adapted to solve signomial programs by solving a sequence of GP approximations. Dinkel *et al.* [30] also used condensation and linearization and their procedure is actually quite similar to the method in Avriel *et al.* [29]. Gochet and Smeers [31] used a cutting plane approach, but solve Program P_z (the convex version of the primal). More recently, Maranas and Floudas [32] described another

algorithm that is used to find the global optimum for a signomial problem. Their method works by expressing the objective and constraints as differences of two convex functions and then using a branch and bound type approach. There have been several new interior point methods, for example, Bricker and Chang [33] and Kortanek *et al.* [34]. The latter in particular is probably one of the best algorithms currently available and the authors report being able to efficiently solve very large problems.

Coming to the dual problem an early approach by Beck and Ecker [35] was to use a variation of the convex simplex method that allowed for blocks of variables to go to zero simultaneously in order to counter problems with differentiability. Blau and Wilde [36] developed another early method that solves for the Kuhn–Tucker optimality conditions, but for the dual problem; it can also handle signomial problems. Kochenberger *et al.* [37] describe a method where they use separable programming for a version with the log-dual objective. Kortanek and No [38] used an interior point approach with affine scaling on the dual. More recently, Rajgopal and Bricker [39] describe a method that is based on a reformulation of the primal as a semi-infinite linear program [40] where the problem is restated with a finite number of variables but infinitely many constraints. Essentially, these constraints may be viewed as linear supports for the original nonlinear constraints. Rather than solve this problem, they use its dual (which is a so-called *generalized linear program*), and implement a column generation approach to solve it. The authors report that their method avoids all of the computational problems typically associated with dual-based algorithms.

Finally, it is worth mentioning that in addition to the open availability of codes for several GP algorithms [34,39] there are also implementations on MATLAB that are available to solve GP problems [41,42].

SUMMARY

GP is a mature area within the broader area of NLP. Most of the important theoretical results relevant to GP as well as

major generalizations and extensions were developed during roughly a 15-year span of time starting in the mid-1960s. Two comprehensive sources that capture the important work during that period in terms of theory, algorithms, and applications are the bibliographic note by Rijckaert and Martens [43] and the review article by Ecker [44].

While the pace of development since then has been slower, extensions and new insights, as well as new applications and algorithms, continue to be reported regularly in the literature. As examples of later extensions, Choi and Bricker [45] have an interesting article that extends GP to the case where some of the variables are discrete. Uncertainty in GP has also attracted the attention of some researchers; for example, Jagannathan [46] examines a stochastic GP with recourse, while Liu [47] considers the case where coefficients and exponents are assumed to lie within their own intervals as opposed to taking on fixed values. Cao [7,48] combines GP with fuzzy mathematics to develop the area of fuzzy GP. Recently Hsiung *et al.* [49] incorporate parameter uncertainty and develop a method for addressing robust GP where the optimization is over the worst-case scenario. Another interesting theoretical article by Peterson [50] attempts to relate GP duality to regular Lagrangian duality and duality for parametric programming (in the form of parameter perturbations).

Development of new applications has possibly been the biggest area of emphasis within GP over the last 10–15 years. There is in some circles a misconception that GP is a narrow subset of NLP with a rigid format requirement that precludes most optimization problems from being addressed by this technique. As the literature indicates, this is not true; new applications for GP continue to be regularly reported beyond the initial ones in engineering design and the multitude of areas cited in Rijckaert and Martens [43]. These applications span many fields including mathematics and statistics [51–53], manufacturing [54–57], production and inventory control [58–61], and most recently, electronics and computer engineering [62–65]. With the availability of good software as well, this trend will likely continue in the near future.

GERMAN OPERATIONS RESEARCH SOCIETY (GOR) (GESELLSCHAFT FÜR OPERATIONS RESEARCH)

HORST W. HAMACHER
Department of Mathematics,
University of Kaiserslautern,
Kaiserslautern, Germany

In Germany, operations research has a long tradition, manifested since the 1950 s in various organization forms, and—until the German reunification in 1990—in two different countries. Excellent surveys on the history of OR in the two Germanies can be found in the articles of Müller-Merbach and Lassmann (OR News 36 (2009), pp. 6–12). Part of this history is the existence of several predecessor OR societies which, in 1998, led to the foundation of the GOR as the single OR society. Since then, six presidents have been serving: Peter Kleinschmidt (1998), Ulrich Derigs (1999–2000), Uwe Zimmermann (2001–2002), Gerhard Wäscher (2003–2006), Thomas Spengler (2007–2008), and Horst W. Hamacher (2009–2010). The GOR with its 1100 individual and corporate members is the second largest OR society in Europe. It is a member of IFORS and EURO and has recently, in July 2009, been organizer of the EURO conference in Bonn with some 2400 participants.

One of the main features and strengths of the GOR is its—never ending—effort to bring together various streams, in particular OR practitioners and basic researchers.

The first important tool in this effort is our publication instruments. The *OR News* appearing thrice per year and edited since its beginning by Joachim Minnemann is—similar to its US counterpart ORMS Today—an excellent source of information

on OR events in the world and on OR articles which are accessible to laymen as well as specialists. The professional journals, *Operations Research Spectrum* and *Mathematical Methods of Operations Research* (currently edited by Stefan Minner and Alexander Martin, respectively) are well established in the international OR community. The former journal is devoted to the practice of OR while the latter focuses on the development of new mathematical methods within OR. An excellent opportunity to meet and exchange ideas is the *annual GOR conference*, which is always taking place in the first week of September. Every 4 years this conference is organized as a trinational event with our sister organizations in Austria and Switzerland. Refereed extended abstracts of selected papers presented at these meeting are published in the Springer Series *Operations Research Proceedings*.

The thirteen working groups compose another invaluable instrument to unify practice and theory within the GOR. In general, the groups meet twice a year in workshops to exchange ideas, discuss problems posed by industry and administrations, or to present new results. These meetings are in general open to nonmembers of the GOR. Each issue of the OR News contains an update of the current activities of the GOR working groups.

In order to recognize excellence, five types of GOR awards have been established: Bachelor's, Diploma/Master's, Ph.D., Scientific, and Enterprise Awards. With the exception of the first one, they are awarded during the annual GOR conference and are generously supported by sponsors who at present include INFORM GmbH, GAMS, BASF, and Springer Publishers.

GOMORY CUTS

RICARDO FUKASAWA
Department of Combinatorics and
Optimization, University of
Waterloo, Waterloo, Ontario,
Canada

Gomory fractional (GF) cuts were introduced in 1958 with an announcement by Ralph E. Gomory [1] of an “algorithm for integer solutions to linear programs (LPs)” (a full version of the algorithm appears in Ref. 2), which gave a finite cutting-plane algorithm for pure integer programming. In a later paper [3], he also introduced the so called *Gomory mixed-integer (GMI)* cuts. Since then, the field of (mixed-) integer programming has developed immensely, but throughout the years and up to this day, Gomory’s fractional cuts, the closely related Chvátal–Gomory (CG) cuts, and the mixed-integer cuts of Gomory play a significant role in much of the research that is done in the field. The purpose of this paper is to do a brief survey of the research that has been carried out around Gomory cuts throughout the years. The interested reader is also referred to some surveys on general cutting planes [4–6], as well as related articles about cutting planes (in the section titled “Cutting Planes”) in this encyclopedia.

The organization of this paper is as follows. In what remains of this section, we define what are the GF cuts, the closely related CG cuts, and the GMI cuts. We then introduce mixed-integer rounding (MIR) cuts and explore their relationship with GMI cuts. The section titled “Closures and Rank” is devoted to defining and reviewing some of the results related to rank and closure for each of the classes of cuts. The section titled “Special Cases, Variations, Strengthening, and Others” surveys some variations, special cases, and relations that Gomory cuts have with other types of cuts. The section titled “Implementation and Computational Aspects” is devoted to computational issues, while the section titled “Multirow Gomory

Cuts” talks about the recent interest in the so-called *multirow Gomory cuts*.

Throughout this paper, we refer to the following general mixed-integer sets:

$$P_I = \{(x, z) \in \mathbb{Z}_+^n \times \mathbb{R}_+^p : Ax + Dz \leq b\} \quad (1)$$

and

$$Q_I = \{(x, z) \in \mathbb{Z}^n \times \mathbb{R}^p : Ax + Dz \leq b\}. \quad (2)$$

GOMORY’S FRACTIONAL CUTS

Gomory’s fractional cuts are defined for the pure integer case and when all variables are assumed to be nonnegative, that is, they are cuts that are valid for the following set (P_I with $p = 0$):

$$P_I = \{x \in \mathbb{Z}_+^n : Ax \leq b\}. \quad (3)$$

In addition, Gomory’s fractional cuts were derived in Ref. 1 when the constraints were in equality form. Since, in the context of mixed-integer programming, it is assumed that all data is rational, we may assume that A and b are integral and introduce slack variables to obtain $P'_I = \{(x, s) \in \mathbb{Z}_+^{n+m} : Ax + s = b\} := \{z \in \mathbb{Z}_+^{n+m} : Gz = b\}$, where $z = (x, s)$ and $G = (A, I)$.

We can relax P'_I by multiplying all equations by a vector $u \in \mathbb{R}^m$ to obtain the set $\{z \in \mathbb{Z}_+^{n+m} : uGz = ub\}$. We can further relax this set to obtain the set $P_G = \{z \in \mathbb{Z}_+^{n+m} : uGz \equiv ub \pmod{1}\}$, which means that uGz and ub differ by an integer. Moreover, let $f(a) := a - \lfloor a \rfloor$ denote the fractional part of a real number a . Now since P_G is expressed in terms of a modular equation, it can be rewritten as $P_G = \{z \in \mathbb{Z}_+^{n+m} : f(uG)z \equiv f(ub) \pmod{1}\}$, where $f(uG)$ is the vector obtained by taking the fractional part of each component of uG . Notice that $f(uG) \geq 0$ and $z \geq 0$, hence $f(uG)z \geq 0$. Finally, since $f(uG)z \equiv f(ub) \pmod{1}$ and $f(uG)z \geq 0$, then $f(uG)z$ must be equal to

$f(ub) + k$ for some integer $k \geq 0$. This argument shows that the following inequality is valid for P_G :

$$f(uG)z \geq f(ub). \quad (4)$$

If we substitute in Equation (4) the identities $f(uG) = uG - \lfloor uG \rfloor$, $f(ub) = ub - \lfloor ub \rfloor$, and $s = b - Ax$, we obtain the *GF cut* on the original x variables:

$$\lfloor uA \rfloor x - \lfloor u \rfloor Ax \leq \lfloor ub \rfloor - \lfloor u \rfloor b. \quad (5)$$

We would like to point out that GF cuts are defined here by using any multiplier $u \in \mathbb{R}^m$, but Gomory's cutting-plane algorithm uses a specific set of multipliers u that are associated with basic feasible solutions of $P' = \{(x, s) \in \mathbb{R}_+^{n+m} : Ax + s = b\}$. For more details on this distinction and its implications, see Ref. 7.

CHVÁTAL-GOMORY CUTS

CG cuts were defined by Chvátal [8] and are also defined for the pure integer case (that is, when $p = 0$). However, unlike in the case of the GF cuts, CG cuts are valid for the following set

$$Q_I = \{x \in \mathbb{Z}^n : Ax \leq b\}, \quad (6)$$

that is, even when there is no nonnegativity assumption on the variables. Similar to Gomory's fractional cuts, we can aggregate the constraints in Q_I by using a multiplier $u \in \mathbb{R}_+^m$ to obtain the relaxation $\{x \in \mathbb{Z}^n : uAx \leq ub\}$. Now, if $uA \in \mathbb{Z}^n$, then $uAx \in \mathbb{Z}$ and hence the following CG cut is valid for Q_I .

$$uAx \leq \lfloor ub \rfloor. \quad (7)$$

If our original feasible set is described as

$$P_I = \{x \in \mathbb{Z}_+^n : Ax \leq b\}, \quad (8)$$

that is, with a nonnegativity assumption on the variables, a slightly different argument can be used to derive the CG cut.

Note that if $Q_I = \{x \in \mathbb{Z}^n : Ax \leq b ; -x \leq 0\}$, that is, if the nonnegativity constraints

are included in the constraint matrix, rather than explicitly imposed, we have that any cut of the form (7) is

$$(uA - \lambda)x \leq \lfloor ub \rfloor,$$

where $(u, \lambda) \in \mathbb{R}_+^{m+n}$ are the CG multipliers.

In this case, we do not need to require that $uA \in \mathbb{Z}^n$, because, since $x \geq 0$, $\lfloor uA \rfloor x \leq uAx \leq ub$ and, since $\lfloor uA \rfloor x \in \mathbb{Z}$, the CG cut

$$\lfloor uA \rfloor x \leq \lfloor ub \rfloor \quad (9)$$

is valid for P_I . Equivalently, we require $(uA - \lambda) \in \mathbb{Z}^n$ and any nondominated CG cut will have $\lambda = uA - \lfloor uA \rfloor$, which leads to Equation (9).

It is easy to see that any CG cut of the form (9) can be obtained as a CG cut of the form (7) when the nonnegativity constraints are not explicitly imposed, but are present in the constraint matrix. Conversely, under the nonnegativity assumption, any cut of the form (7) can either be obtained as a cut of the form (9) or is dominated by one.

The name CG cuts comes from the fact that, under the nonnegativity assumption on the variables, any cut of the form (5) can be obtained as a cut of the form (9) and vice versa (see Refs 7 and 9 for more details). This is the reason why these two types of cuts are often said to be equivalent. However, note that the cut (7) cannot always be obtained as a cut of the form (5), since the latter requires the nonnegativity assumption.

GOMORY MIXED-INTEGER CUTS

The arguments for the derivation of CG cuts and GF cuts rely on the fact that all variables are required to be integral and therefore the same arguments cannot be directly applied when we have a mixed-integer set

$$P_I = \{(x, z) \in \mathbb{Z}_+^n \times \mathbb{R}_+^p : Ax + Dz \leq b\}. \quad (10)$$

By adding slack variables, we obtain the following set in equality form

$$P'_I = \{(x, y) \in \mathbb{Z}_+^n \times \mathbb{R}_+^{p+m} : Ax + Gy = b\}, \quad (11)$$

where $G = (D, I)$ and $y = (z, s)$. We again multiply the equations by a vector $u \in \mathbb{R}^m$ to obtain the set

$$P'_I(u) = \{(x, y) \in \mathbb{Z}_+^n \times \mathbb{R}_+^{p+m} : \bar{a}x + \bar{g}y = \bar{b}\}, \quad (12)$$

where $\bar{a} = uA$, $\bar{g} = uG$, and $\bar{b} = ub$ and we assume that $f(\bar{b}) > 0$. Let $f_i = f(\bar{a}_i)$ and $f_0 = f(\bar{b})$. We are now ready to derive the GMI cut. Notice that $P'_I(u)$ can be rewritten as

$$\begin{aligned} & \sum_{i: f_i \leq f_0} f_i x_i + \sum_{i: f_i > f_0} (f_i - 1)x_i + \bar{g}y \\ &= \left(\lfloor \bar{b} \rfloor - \sum_{i=1}^n \lfloor \bar{a}_i \rfloor x_i - \sum_{i: f_i > f_0} x_i \right) + f_0. \end{aligned}$$

Since $k := \left(\lfloor \bar{b} \rfloor - \sum_{i=1}^n \lfloor \bar{a}_i \rfloor x_i - \sum_{i: f_i > f_0} x_i \right) \in \mathbb{Z}$, then either $k \leq -1$, in which case

$$- \sum_{i: f_i \leq f_0} \frac{f_i}{1-f_0} x_i + \sum_{i: f_i > f_0} \frac{1-f_i}{1-f_0} x_i - \frac{\bar{g}}{1-f_0} y \geq 1 \quad (13)$$

or $k \geq 0$, in which case

$$\sum_{i: f_i \leq f_0} \frac{f_i}{f_0} x_i + \sum_{i: f_i > f_0} \frac{f_i - 1}{f_0} x_i + \frac{\bar{g}}{f_0} y \geq 1. \quad (14)$$

Since both these cuts are of the form $a^1 w \geq 1$ and $a^2 w \geq 1$, and $w \geq 0$, then the cut $\sum_j \max\{a_j^1, a_j^2\} w_j \geq 1$ is valid for $P'_I(u)$ and hence valid for P'_I .

Therefore, the following inequality, called the *GMI cut*, is valid for P'_I

$$\begin{aligned} & \sum_{i: f_i \leq f_0} \frac{f_i}{f_0} x_i + \sum_{i: f_i > f_0} \frac{1-f_i}{1-f_0} x_i + \sum_{j: \bar{g}_j \geq 0} \frac{\bar{g}_j}{f_0} y_j \\ & - \sum_{j: \bar{g}_j < 0} \frac{\bar{g}_j}{1-f_0} y_j \geq 1 \end{aligned} \quad (15)$$

(for this and other derivations of this cut see Refs 2, 4, 9).

It is worth noting that, in the pure integer case, the GMI cut is still valid and is of the form

$$\sum_{i: f_i \leq f_0} \frac{f_i}{f_0} x_i + \sum_{i: f_i > f_0} \frac{1-f_i}{1-f_0} x_i \geq 1. \quad (16)$$

We can compare that cut with the GF cut

$$\sum_{i=1}^n \frac{f_i}{f_0} x_i \geq 1$$

and notice that when $f_i > f_0$, we have that $\frac{1-f_i}{1-f_0} < \frac{f_i}{f_0}$. Therefore, the GMI cut dominates the GF cut in the pure integer case.

MIXED-INTEGER ROUNDING CUTS

In this section, we introduce MIR cuts. Notice that this class of cuts is the topic of another completely independent article of this encyclopedia. However, MIR cuts are so closely related to GMI cuts that it is worth devoting some attention to this relationship in more detail. First, we need to point out that there are multiple cuts that are called *MIR* cuts. We use here the definition from Ref. 10. See also Refs 9, 11–13 for other references on MIR cuts. Consider the general mixed-integer set

$$Q_I = \{(x, z) \in \mathbb{Z}^n \times \mathbb{R}^p : A'x + D'z \leq b'\}. \quad (17)$$

Suppose we multiply the inequalities in Equation (17) by two different vectors $\mu^1, \mu^2 \in \mathbb{R}_+^{n'}$, where $\mu^1 D' = \mu^2 D'$ and $(\mu^2 - \mu^1)A' \in \mathbb{Z}^n$ then the inequality

$$\begin{aligned} & (\mu^2 - \mu^1)A'x \\ & + \frac{\mu^1 A'x + \mu^1 D'z - \mu^1 b'}{1 - ((\mu^2 b' - \mu^1 b') - \lfloor \mu^2 b' - \mu^1 b' \rfloor)} \\ & \leq \lfloor \mu^2 b' - \mu^1 b' \rfloor \end{aligned} \quad (18)$$

is called the *MIR inequality* and is valid for Q_I . Since MIR cuts are the subject of another article titled of this encyclopedia, we will refrain from proving that the MIR inequality is valid for Q_I . We will instead point out that Q_I does not explicitly require the variables to be nonnegative. However, if $A' = [A, -I, \mathbf{0}]^T$, $D' = [D, \mathbf{0}, -I]^T$, and $b' = [b, \mathbf{0}, \mathbf{0}]^T$ (that is, the nonnegativity constraints are included in $A'x + D'z \leq b'$), then $Q_I = P_I$ and the MIR inequalities (Eq. 18) can be derived as *GMI inequalities* (Eq. 15) and vice versa.

To see how, let us assume that the nonnegativity constraints are contained in the inequalities $A'x + D'z \leq b'$. Therefore, the multipliers μ^1 and μ^2 can be written as $\mu^1 = [\mu_o^1, \mu_x^1, \mu_z^1]^T$ and $\mu^2 = [\mu_o^2, \mu_x^2, \mu_z^2]^T$, where μ_o^i is the multiplier for the constraints $Ax + Dz \leq b$, μ_x^i for the $-x \leq 0$ constraints and μ_z^i for the $-z \leq 0$ constraints, for $i = 1, 2$. Notice that even if we vary μ^1 and μ^2 , as long as $\mu^2 - \mu^1$ does not change, the only term that varies in Equation (18) is the numerator of the fraction. Therefore, since $Ax + Dz - b' \leq 0$, and $\mu^1 \geq 0$, if we increase μ^1 and μ^2 by the same amount, we get a weaker inequality. So, we may assume that for every i , either $\mu_o^1 = 0$ or $\mu_o^2 = 0$. So we may define $\mu = \mu^1 - \mu^2 \in \mathbb{R}^{m'}$ with no sign restriction and $\mu^1 = \mu^+$ and $\mu^2 = (-\mu)^+$, with Equation (18) becoming

$$-\mu A'x + (\mu)^+ \frac{Ax + Dz - b'}{1 - (-\mu b' - \lfloor -\mu b' \rfloor)} \leq \lfloor -\mu b' \rfloor. \quad (19)$$

Now, notice that $\lfloor -\mu b' \rfloor = -\lceil \mu b' \rceil$, so we can rewrite Equation (19) as

$$\begin{aligned} &(\mu b' - \lfloor \mu b' \rfloor) \mu A'x + (\mu)^+(b' - A'x - D'z) \\ &\geq (\mu b' - \lfloor \mu b' \rfloor) \lceil \mu b' \rceil. \end{aligned} \quad (20)$$

Moreover, if we expand μ , A' , D' , and b' , we get

$$\begin{aligned} &(\mu_o b - \lfloor \mu_o b \rfloor)(\mu_o A - \mu_x)x + (\mu_o)^+(b - Ax - Dz) \\ &+ (\mu_x)^+x + (\mu_z)^+z \geq (\mu_o b - \lfloor \mu_o b \rfloor) \lceil \mu_o b \rceil. \end{aligned} \quad (21)$$

But recall that $\mu A' \in \mathbb{Z}^n$ and $\mu D' = 0$. This means that $\mu_o A - \mu_x \in \mathbb{Z}^n$ and that $\mu_o D - \mu_z = 0$. Now $\mu_o A - \mu_x \in \mathbb{Z}^n$ implies that $\mu_x = \hat{a} + t$ for some integral vector $t \in \mathbb{Z}^n$, where $\hat{a} = \mu_o A - \lfloor \mu_o A \rfloor$. If $t_i \geq 1$, then $(\mu_x)_i \geq 1$ and hence $(\mu_x)_i^+ = (\mu_x)_i$. So decreasing t_i to 0 decreases the coefficient of x_i . If $t_i < -1$, then $(\mu_x)_i \leq -1$ and hence $(\mu_x)_i^+ = 0$. So the coefficient of x_i can be decreased by increasing t_i . Hence $t_i \in \{0, -1\}$ for any nondominated MIR inequality.

Defining $\mu_o b - \lfloor \mu_o b \rfloor = f_0$, we can rewrite Equation (21) as

$$\begin{aligned} &(\mu_x)^+x - f_0 \mu_x x + f_0 \hat{a} x + f_0 \lfloor \mu_o A \rfloor x + (\mu_o)^+ \\ &\times (b - Ax - Dz) + (\mu_o D)^+ z \geq f_0 \lceil \mu_o b \rceil. \end{aligned} \quad (22)$$

When $t_i = 0$, we have that $(\mu_x)_i = \hat{a}_i$ so the coefficient of x_i in the first three terms of Equation (22) is $\hat{a}_i$. When $t_i = -1$, we have that $(\mu_x)_i = \hat{a}_i - 1$, so the coefficient of x_i in the first three terms of Equation (22) is f_0 . Therefore, it is easy to see that any nondominated MIR inequality will have the form

$$\begin{aligned} &\min\{\mu_o A - \lfloor \mu_o A \rfloor, f_0 \mathbf{1}\}x + f_0 \lfloor \mu_o A \rfloor x + (\mu_o)^+ \\ &\times (b - Ax - Dz) + (\mu_o D)^+ z \geq f_0 \lceil \mu_o b \rceil. \end{aligned} \quad (23)$$

It is not hard to see, after some algebraic manipulations, that the MIR inequality (Eq. 23) is exactly the GMI inequality (Eq. 15) that we obtain if we do as follows:

1. add slack variables s to $Ax + Dz \leq b$;
2. use μ_o as a multiplier for $Ax + Dz + s = b$ and obtain Equation (15);
3. multiply Equation (15) by $f_0(1 - f_0)$, add it to f_0 times $\mu_o Ax + \mu_o Dz + \mu_o s = \mu_o b$ and substitute out the slack variables.

Therefore, under the nonnegativity assumption, MIR inequalities and GMI inequalities are said to be equivalent. However, note that Equation (15) was derived using the nonnegativity of the variables, while Equation (18) was not. In that sense, the relationship between MIR inequalities and GMI inequalities is analogous to the relationship between CG cuts and GF cuts. For more details, see Refs 7, 14, 15.

CLOSURES AND RANK

The concepts of the *elementary closure* and *rank* were introduced by Chvátal [16] for CG cuts and are important topics, which have received much attention since they are theoretical concepts that give an indication of the strength of a family of cuts or alternatively a measure of its complexity. We now define these concepts for Gomory cuts and survey a few of the results that are known for ranks and closures of polyhedra.

For each of the cuts presented in the previous section, let P denote the polyhedron obtained by dropping the integrality requirements on the sets from which the cuts were derived (P_I with $p = 0$ for GF,

Q_I with $p = 0$ for CG , P_I for GMI). Notice that all the cuts presented in the previous section were derived by aggregating the set of linear constraints in P with some multipliers $u \in \mathbb{R}^m$ ($u \in \mathbb{R}_+^m$ in the case of CG cuts). This observation means that, once the multipliers are fixed, the derivation of the cuts is unique and it makes sense to define $GF(u, P)$, $CG(u, P)$, and $GMI(u, P)$ as the Gomory fractional/ CG / GMI cut obtained by using u as multipliers to aggregate the linear constraints in P . This immediately gives rise to families of these inequalities $F_{GF}(P) := \{GF(u, P) : u \in \mathbb{R}^m\}$, $F_{CG}(P) := \{CG(u, P) : u \in \mathbb{R}_+^m\}$, and $F_{GMI}(P) := \{GMI(u, P) : u \in \mathbb{R}^m\}$ obtained by considering all possible values of u .

We can now define

$$P_{CG}^1 = \{x \in P : x \text{ satisfies all inequalities in } F_{CG}(P)\} \quad (24)$$

as the *rank-1 CG -closure* of P , and one can similarly define P_{GF}^1 and P_{GMI}^1 , which are the *rank-1 GF -closure* and *rank-1 GMI closure* of P . The rank-1 closure is also called the *elementary closure* of a given family of cuts derived from P and valid for P_I .

It is also useful to apply the same concept recursively and define for $k \geq 1$:

$$P_{CG}^k = \{x \in P_{CG}^{k-1} : x \text{ satisfies all inequalities in } F_{CG}(P_{CG}^{k-1})\} \quad (25)$$

as the *rank- k CG -closure* where $P_{CG}^0 = P$. Similarly define the *rank- k GF closure* P_{GF}^k and the *rank- k GMI closure* P_{GMI}^k . Note that (25) is not well-defined unless $P_{CG}^1/P_{GF}^1/P_{GMI}^1$ is a polyhedron. This is in fact true and will be dealt with in the subsection “Seperation and Polyhedrality of Closures”. With that, we can also define the CG rank of an inequality being k if it is valid for P_{CG}^k but not for P_{CG}^{k-1} . Finally, we say that the CG rank of a class of inequalities is the maximum CG rank among all inequalities in that class and we say that the rank of a polyhedron P is the highest rank among all inequalities defining $\text{conv}(P \cap \mathbb{Z}^n)$ (we can derive similar definitions for GF / GMI ranks).

Relationships Between Closures

As mentioned earlier, GF cuts are equivalent to CG cuts in the presence of nonnegativity constraints and, therefore, the immediate result is that $P_{CG}^1 = P_{GF}^1$. Similarly, in the mixed-integer case, the rank-1 GMI closure is the same as the rank-1 MIR closure, under the nonnegativity assumption. In addition, if the variables are nonnegative, the rank-1 GMI closure is the same as the rank-1 split closure of P , obtained from another important family of cuts: split cuts [17,18]. Because of this fact, GMI , MIR , and split cuts are considered “equivalent” under the nonnegativity assumption. For more details on MIR and split cuts, see the article title and ***Split Cuts*** in this encyclopedia. As shown before, in the pure integer case, the GMI cut dominates the GF cut, which means that $P_{GMI}^1 \subseteq P_{CG}^1$. In addition, the inclusion is strict, so not only does the individual GMI cut derived using a specific set of multipliers dominate the CG cut using the same multiplier but the class of rank- k GMI cuts is also “stronger” than the class of rank- k CG cuts. In fact, when compared to several different classes of cuts, the rank-1 GMI closure is stronger than most of the other rank-1 closures. For more details on these and other related results see the detailed study on the relationship between several elementary closures by Cornuéjols and Li [7].

Separation and Polyhedrality of Closures

Note that the way rank-1 CG / GMI closures are defined, they consist of infinitely many inequalities. Therefore, one natural question is whether there exists a finite set of those inequalities that suffice to describe P_{CG}^1 , P_{GF}^1 , and P_{GMI}^1 .

The answer is positive in both cases. In the pure integer case, P_{CG}^1 (and hence P_{GF}^1) was shown to be polyhedral by Chvátal [16] and Schrijver [19,20]. In addition, Bockmayr and Eisenbrand [21] show that, in fixed dimension, the number of inequalities needed to describe P_{CG}^1 is polynomial in the size of the input. In the pure and mixed-integer case, P_{GMI}^1 was shown to be polyhedral by Cook *et al.* [18], in terms of the split-closure (equivalent to P_{GMI}^1 under nonnegativity).

Alternative proofs of this fact were later given by Andersen *et al.* [22,23], Vielma [24], and Dash *et al.* [15].

Now the number of inequalities required to describe P_{CG}^1 , P_{GF}^1 , and P_{GMI}^1 is usually very large and, therefore, one natural question that arises is to solve the separation problem, that is, given a point $x^* \in P$, either show that $x^* \in P_{CG}^1/P_{GF}^1/P_{GMI}^1$ or provide a hyperplane separating x^* from $P_{CG}^1/P_{GF}^1/P_{GMI}^1$. Unfortunately, the separation problem cannot be solved in polynomial time unless $P = NP$: Separation over P_{CG}^1 is shown to be strongly NP-complete by Eisenbrand [25]. Even if P is contained in the nonnegative orthant, separation over P_{CG}^1 (equivalently over P_{GF}^1), and over P_{GMI}^1 , was shown to be strongly NP-complete by Caprara and Letchford [26]. In spite of that, in the case of set covering, Bienstock and Zückerberg [27] have recently shown that one can approximate the rank- k CG closure to an arbitrary fixed precision in polynomial time (for a fixed k).

Bounds on the Rank

Another interesting question that has received significant research attention relates to obtaining bounds on the rank of polyhedra. These bounds give an idea on how much does each family of cutting planes approximate the convex hull of integer solutions.

For pure integer programs (IPs), it is well known [8,19] that all valid inequalities have finite CG rank. However, the rank of certain inequalities can be arbitrarily large, even in dimension 2 (see Chvátal [8]). This implies that, even if one could generate and add all possible rank-1 cuts, this procedure needs to be repeated an arbitrarily large number of times to obtain the convex hull, which gives an indication of how hard it is to solve integer programs by using only CG cuts.

Cook *et al.* [28] and Gerards [29] show that there is an upper bound on the CG-rank that only depends on the coefficients of the constraint matrix (not on the right-hand side); see Refs 9 and 20. There are, however, special cases that have some more reasonable bounds on the CG rank of polyhedra. For

problems where P is contained in the 0/1 cube, Bockmayr and Eisenbrand [30] give a bound of $O(n^3 \log n)$ on the CG rank of a polyhedron, where n is the number of integer variables. This bound was later improved to $O(n^2 \log n^{n/2})$ by Bockmayr *et al.* [31] and then to $O(n^2 \log n)$ by Eisenbrand and Schulz [32]. In that same paper, they give a different upper bound of $n + \|c\|_1$ on the rank of any inequality $cx \leq \delta$ (with $c \in \mathbb{Z}^n$) valid for the integer hull of P . A very similar bound was obtained by Chvátal *et al.* [33] for monotone polyhedra.

In that same paper, Chvátal *et al.* [33] also give an example of a polyhedron P with a CG rank of n (where n is the number of variables), thereby showing that the lower bound on the CG-rank of polyhedra is n . Several other results are known about rank of polyhedra. For instance, Hartmann [34] gives conditions under which an inequality has rank greater than 1 and Eisenbrand and Schulz [32] give a lower bound on the rank of value $(1 + \epsilon)n$ for some $\epsilon > 0$.

These results on the rank are for CG cuts in the pure integer case and do not immediately translate to the mixed-integer case. For instance, Cook *et al.* [18] give an example of a simple mixed-integer program (MIP) that has infinite GMI-rank, which means that even if we add all possible GMI cuts at every round of cut generation, we still do not get even a finite algorithm for solving a very simple MIP.

However, like in the case of the CG rank, the GMI-rank becomes much smaller when the polyhedra are contained in the 0/1 cube. In particular, Cornuéjols and Li [35] show that for a mixed-integer program where all the n integer variables are restricted to be binary the GMI rank of the polyhedron P is bounded above by n . This result actually follows from the result of Balas [17] on facial disjunctive programs and is best possible as there exists a lower bound of n given by Cornuéjols and Li [35] themselves. The example they use to provide the lower bound is exactly the same example proposed for the CG-rank by Chvátal *et al.* [33]. Notice that, in particular, these results also imply that, for pure 0–1 integer programs, the GMI-rank of polyhedra has an upper bound of n , in

contrast with the CG rank for which only an upper bound of $O(n^2 \log n)$ is currently known.

SPECIAL CASES, VARIATIONS, STRENGTHENING, AND OTHERS

The importance of CG and GMI cuts led several researchers to consider different special cases, variations, and ways to strengthen these cuts. This section highlights a few of these endeavors.

$\{0, \frac{1}{2}\}$ -Cuts and mod- k Cuts

The term $\{0, \frac{1}{2}\}$ -CG cuts ($\{0, \frac{1}{2}\}$ -cuts for short) was introduced by Caprara and Fischetti [36]. The idea of $\{0, \frac{1}{2}\}$ -cuts is to restrict the multipliers $u \in \mathbb{R}_+^m$ used to aggregate the linear constraints of the LP relaxation to be in the set $\{0, \frac{1}{2}\}$. The importance of this special case of Gomory cuts is that many classes of inequalities for combinatorial optimization problems are $\{0, \frac{1}{2}\}$ -cuts, for example, comb inequalities for the traveling salesman problem (TSP). In Ref. 36, it was shown that, even though the CG multipliers are very restricted, separation of $\{0, \frac{1}{2}\}$ -cuts remains strongly NP-hard. In Ref. 26, the authors show that, even under the nonnegativity assumption, separation of $\{0, \frac{1}{2}\}$ -cuts remains strongly NP-hard. Recently, Letchford *et al.* [37] have shown that, even if we restrict ourselves to $\{0, 1\}$ problems and allow some additional structure like set-packing, the separation of $\{0, \frac{1}{2}\}$ -cuts remains strongly NP-hard.

Nevertheless, computationally, Andreello *et al.* [38] show that $\{0, \frac{1}{2}\}$ -cuts can significantly decrease the solution time of branch-and-cut codes for some specific combinatorial optimization problems. Moreover, there are some positive theoretical results involving $\{0, \frac{1}{2}\}$ -cuts.

In order to introduce these results, let us first introduce the mod- k cuts, which generalize $\{0, \frac{1}{2}\}$ -cuts. The mod- k cuts are CG cuts where the multipliers $u \in \mathbb{R}_+^m$ used to aggregate the linear constraints of the LP relaxation are restricted to be in the set $\{0, \frac{1}{k}, \dots, \frac{k-1}{k}\}$ for some integer $k > 1$. It

is not hard to see that all nondominated CG cuts can be written as a mod- k cuts for some k . Clearly, the NP-hardness results for $\{0, \frac{1}{2}\}$ -cuts immediately imply that the separation of mod- k cuts is also NP-hard. This particular class of cuts was studied by Caprara *et al.* [39] where they showed that if we only restrict ourselves to maximally violated mod- k cuts, then we can solve the separation problem in polynomial time. This positive result obviously extends to $\{0, \frac{1}{2}\}$ -cuts and generalizes a result of Applegate *et al.* [40] and Fleischer and Tardos [41] for the separation of maximally violated comb inequalities for the TSP. Later on, Letchford [42] extended their results to show that *totally tight* mod- k -cuts (of which maximally violated mod- k cuts are a subclass) can also be separated in polynomial time. Though Caprara *et al.* [39] had already derived this result for totally tight mod- k cuts as well, in Caprara *et al.*'s result one must specify in advance which class of mod- k cuts one wishes to separate (i.e, we must know what k is in advance). Letchford's results show that this is actually not necessary.

Another generalization of $\{0, \frac{1}{2}\}$ -cuts are binary clutter inequalities [43] for which separation is again strongly NP-hard, but polynomially solvable under certain conditions (this, in particular, gives other conditions under which $\{0, \frac{1}{2}\}$ -cuts can be separated in polynomial time).

Projected CG Cuts

Notice that CG cuts are only defined for pure integer programs. However, if one considers the general mixed integer set

$$P_I = \{(x, z) \in \mathbb{Z}_+^n \times \mathbb{R}_+^p : Ax + Dz \leq b\}, \quad (26)$$

one can still use CG cuts to obtain important cuts for P_I . The idea is as follows. Let P be the polyhedron obtained by dropping the integrality constraints from P_I , that is,

$$P = \{(x, z) \in \mathbb{R}_+^n \times \mathbb{R}_+^p : Ax + Dz \leq b\}. \quad (27)$$

Now, define $P(x)$ as the projection of P in the x -space. Finally, define $P_I(x) := P(x) \cap \mathbb{Z}^n$.

Then, since $P_I(x)$ is a pure integer set, one can generate CG cuts for it. Moreover, due to the structure of how $P(x)$ is obtained, it is easy to see that any CG cut generated for $P_I(x)$ is a cut that is valid for P_I . For more details on this, see Ref. 44. In particular, the authors of that paper also show that such cuts correspond to a specific class of split cuts (and hence to a specific class of GMI cuts). Another interesting result related to projected CG cuts is that, if all the continuous variables have a zero coefficient in the objective function, then one can optimize over the MIP by using a finite number of rounds of projected CG cuts.

Other Variations

There have been several other variations, strengthenings, and studies of Gomory cuts. We mention a few of them as follows:

- k -cuts [45] are GMI cuts obtained from integer multiples of tableau rows. The above paper analyzes when k -cuts are better than the simple GMI cuts obtained by a tableau row and give a study when k -cuts seem to help in practice.
- In reduce-and-split cuts [46], the authors observe that the coefficients of the continuous variables in the GMI cut are an important factor to determine the distance from the cut to the point being cut off. Since this distance is one of the measures of “cut quality,” the authors give an algorithm to try to reduce the coefficients of the continuous variables and show that by doing so there is a significant improvement over only using GMI cuts from tableau rows.
- Balas and Perregard [47] give a precise correspondence between lift-and-project cuts [48] for mixed 0–1 programs, split cuts [18], and GMI cuts. Such correspondence gives rise to the upper bound on the GMI rank of n for pure 0/1 IPs and to an algorithm that tries to obtain better cuts than the GMI cut from a tableau row by looking at GMI cuts obtained from a (possibly infeasible) basis of the tableau.

- Letchford and Lodi [42] show a simple way to strengthen CG cuts, obtaining a cut with CG rank 2.
- Köppe and Weismantel [49] use basis reduction to generate strong GMI cuts.
- Ceria *et al.* [50] consider GMI cuts obtained by aggregating the rows of the optimal tableau from the LP relaxation with integer multipliers.
- Glover and Sherali [51] give a closed-form expression for a cut obtained by repeating the CG procedure several times, thus obtaining a closed form for some CG cuts whose rank is higher than 1.

These are just a few examples and the literature of papers that fall into this same category is enormous and would not fit into the available space we have. Therefore, we refrain from making an exhaustive list of the same.

Gomory Cuts as Group Cuts

In this section, we introduce Gomory’s corner and group relaxations, which are important relaxations for MIPs. The *corner relaxation* is a common relaxation of the feasible region of an MIP, obtained from the system of inequalities defining the tableau rows of the LP relaxation and relaxing the nonnegativity constraints on the basic variables.

Specifically, consider the feasible region for an MIP:

$$\begin{aligned} Ax &= b \\ x &\geq 0 \\ x_i &\in \mathbb{Z}, \forall i \in I \subseteq \{1, \dots, n\}. \end{aligned} \quad (28)$$

The tableau rows from the LP relaxation yield the system:

$$\begin{aligned} x_B &= f + Rx_N \\ x_B, x_N &\geq 0 \\ x_i &\in \mathbb{Z}, \forall i \in I \subseteq \{1, \dots, n\}, \end{aligned} \quad (29)$$

where $f = A_B^{-1}b$ and $R = -A_B^{-1}A_N$. For simplicity, we assume that $I = \{1, \dots, n\}$ and that

$|B| = m$. If we drop the nonnegativity constraints corresponding to variables x_B , we get the *corner relaxation*:

$$\left\{ \begin{array}{l} x_B = f + \sum_{j \in N} r^j x_j \\ x : \quad x_N \geq 0 \\ \quad x_B \in \mathbb{Z}^m \\ \quad x_i \in \mathbb{Z}, \forall i \in N \end{array} \right\}, \quad (30)$$

where r^j are the columns of R .

If we add one variable for every possible element of the group generated by the r^j vectors, we get the master group relaxation. If $m = 1$, we call it the master cyclic group relaxation. For a more thorough discussion on the group problem, corner polyhedron, and master group relaxations, the reader is referred to Refs 52–54 and the article titled ***Inequalities from Group Relaxations*** in this encyclopedia.

Now we call a function ψ valid for the group relaxation if, for every feasible solution x for the group relaxation, we have that $\sum \psi(r)x_r \geq 1$. Valid functions give rise to valid inequalities for Equation (30) and as a consequence valid inequalities to the original MIP. Also, GMI cuts can be obtained by extreme valid functions (the analogous to a facet-defining inequality), which shows that GMI cuts are important in the context of group cuts. We further discuss the importance of GMI cuts in the context of group cuts in the next section.

IMPLEMENTATION AND COMPUTATIONAL ASPECTS

We now turn our attentions to some of the computational aspects and results that are related to Gomory cuts.

Even though there was interest in Gomory cuts after the 1958 paper [1], they were thought to be computationally ineffective for quite some time [12,55]. Among the many criticisms, Gomory cuts were considered to converge very poorly and their use inside a branch-and-cut framework was questioned since it would require some complex bookkeeping because cuts generated in the branch-and-cut tree are not valid for the

whole problem. Much to the surprise of the community, Balas *et al.* [56] showed in 1996 that GMICs can be used effectively within a branch-and-cut framework for 0–1 MIPs. A more detailed and accurate description of the history of the above paper can be found in Ref. 57. In particular, in that paper, they show a way to lift Gomory cuts for 0–1 MIPs so that they become globally valid regardless of where in the branch-and-cut tree are they generated. They also highlight some computational strategies, some of which are still used today, like adding multiple cutting planes at a time to the LP relaxation.

The importance of that paper in reigniting the interest in Gomory cuts as an important tool to solve general MIPs is remarkable. Indeed, currently, the ability to generate GMICs is widely considered an essential part of most MIP solvers [58]. This fact can be evidenced by a series of papers by Bixby *et al.* [59,60] where, among other things, they test which of the features in CPLEX [61] are more important for the solution of MIPs. They tested the average performance degradation on the solution times for a series of benchmark instances. Their conclusions are that “The clear winner in these tests was cutting planes. Disabling this feature resulted in a deterioration of a *factor* of almost 54 in overall performance, a remarkable difference.”, and among the cutting planes “Gomory cuts are the clear winner by this measure.”.

Though it is hard to say what is the exact influence of such a paper in the research efforts of the following years, we believe it is safe to say the Balas *et al.* paper [56] generated a large interest in Gomory cuts decades after their introduction.

In addition to the already mentioned variations and improvements over Gomory cuts, for which several computational tests have been performed, recently there have been some other papers focusing on computational aspects of Gomory cuts, which we highlight below.

Strength of Gomory Cuts

The practical success of Gomory cuts described above comes mostly by using heuristics for generating such cuts inside commercial codes. While their practical success shows the quality of these heuristics, it remains to be answered if we could do a better job in using these (or other) cutting planes. In other words, the natural questions are as follows: How well are we using Gomory cuts? Could we do much better by trying to generate different Gomory cuts or other classes of cuts? In this section, we review some of the efforts to answer such questions.

One answer to those questions has recently been studied by Fischetti and Lodi [62]. In the above paper, they study the effect of rank-1 CG cuts by modeling the separation problem as an MIP. They obtain good results, in particular, being able to solve an open instance of MIPLIB 2003 [63] for the first time. Their approach was later extended [64,65] to pose the separation of GMI cuts (equivalently MIR/split cuts) as an MIP and use them to evaluate the rank-1 GMI closure. Their results also show that there is still much to gain by using rank-1 Gomory cuts if one is able to separate them well or identify the useful ones. Indeed, recently, Dash and Goycoolea [66] proposed a heuristic for generating rank-1 GMI cuts that seems to perform very well in practice.

The papers mentioned above show that it may be worth spending time to generate “better” Gomory cuts. However, one may switch focus and try to generate cuts that are different than Gomory cuts in hopes of improving the practical performance of an MIP solver. However, even though several other classes of cutting planes for integer programs have been proposed throughout the years, the practical success of several of those inequalities when compared to GMI cuts is limited. This has led researchers to investigate if there is an intrinsic reason for this to happen. Indeed, when compared to group cuts, Dash and Günlük [67] show that interpolated subadditive cuts are dominated by GMI cuts (in a probabilistic sense). In addition, they show in Ref. 68 that after adding

GMI cuts for the tableau rows of the LP relaxation, it is often the case that there are no other violated cyclic group cuts from those same tableau rows. In particular, in those instances, one would not gain anything by attempting to add other cyclic group cuts from the same tableau rows in addition to the GMI cuts.

These results are in line with the computational results of Fischetti and Saturni [69], who show that the performance of GMI is seldom improved when using other cyclic group cuts obtained by interpolation (something that Cornuéjols *et al.* [45] also observe for k -cuts instead of cyclic group cuts). Another indication that GMI are the most important cuts among all the cyclic group cuts comes from Gomory *et al.*’s shooting experiment [70], where they computationally show that a random sample of facets of the cyclic group have most of its elements as GMI inequalities.

In contrast, Fischetti and Monaci [71] study the corner relaxation and show that often one can have a significant bound improvement over GMIs if the whole corner/group relaxation is considered (that is considering all the rows of those relaxations simultaneously—not just a single row at a time as in the case of the cyclic group).

Another empirical study of the strength of GMI cuts is performed in Ref. 72, where they show that adding several rounds of GMI cuts based on the initial tableau rows of the LP relaxation often approximates the intersection of the convex hull of integer points of each of those tableau rows well. In other words, even if one could use any cut valid for the convex hull of integer points satisfying one of the tableau rows, there would often be a negligible gain in terms of bounds, thereby showing the strength of GMI cuts even outside the context of group cuts.

All these computational results seem to indicate that, if one is to significantly improve the performance of Gomory cuts, one either needs to consider cuts that are valid for relaxations with several constraints (as opposed to one constraint as is the case of Gomory cuts) or find a way to identify important single-constraint relaxations and

generate Gomory cuts for it. In fact, in the section “Multirow Gomory Cuts,” we discuss recent efforts toward the first alternative, namely, the study of multirow Gomory cuts.

Numerical Issues and Pure Cutting-Plane Algorithm

When designing a computer code to solve a mixed-integer program, several issues start becoming relevant to the accuracy and effectiveness of such code. For a more complete survey on these issues and the progress of mixed-integer programming computations, we refer the reader to Ref. 58.

We now focus on two of these computational issues that are faced by Gomory cuts. The first one is the issue of cut validity. Note that the derivation of Gomory cuts is purely algebraic and hence relies on the accuracy of numerical computations. However, algebraic calculations in computers are usually performed in floating-point arithmetic, which has intrinsic errors. Usually these errors are very small, but even a very small error can cause a big difference in the coefficient obtained in a Gomory cut. For example, the CG cut for $x_1 + 2x_2 \leq 2.005$ is (assuming $x_1, x_2 \in \mathbb{Z}_+$) is $x_1 + 2x_2 \leq 2$. However, if there is an error of 0.01 in the calculations, we may obtain $x_1 + 2x_2 \leq 1.995$ and hence the cut $x_1 + 2x_2 \leq 1$, which may be an invalid cut. Since the generation of an invalid cut may lead to an MIP solver cutting off the optimal solution and returning the incorrect solution, one needs to be careful when implementing Gomory cuts using floating-point arithmetic.

The usual approach taken by MIP solvers is to implement Gomory cuts with care using heuristic rules to try to avoid such numerical problems. However, as reported by Margot [73], modern cutting-plane generators still generate invalid cuts once in a while. Neumaier and Shcherbina [74], Cook *et al.* [75], and Zanette *et al.* [76] propose methods to generate Gomory cuts that will not suffer from these numerical problems by having a structured way to control the error in the floating-point calculations.

Another issue that is often faced when using Gomory cuts (and that is somewhat

related to the issue of accuracy) is that, after adding a few rounds of cuts, the cut coefficients tend to start getting large and the determinant of the basis matrix in the optimal tableau also tends to grow. This can lead to numerical problems in the LP solver and is one of the reasons why commercial solvers tend not to add too many rounds of Gomory cuts and also why there is a common knowledge that pure cutting-plane algorithms using Gomory cuts are ineffective.

Recently, however, the above has been discussed again in Ref. 76, where they show that pure cutting-plane algorithms can actually perform well, provided certain care is taken. They show that, if one is to perform Gomory’s cutting-plane algorithm with the lexicographic dual simplex, a significant improvement can be obtained in the final bound. Moreover, the authors also show that the problem of obtaining large cut coefficients and basis determinants becomes much less pronounced.

In Ref. 77, the authors extend their study to understand what is the relationship between cutting-plane methods and some enumerative schemes, proposing different variants of Gomory’s cutting-plane method. This line of research is extremely recent and shows that there are still several issues (both computational and theoretical) that we do not fully understand with respect to Gomory cuts and the cutting-plane method.

MULTIROW GOMORY CUTS

We now focus on an extension of Gomory cuts that consider multiple-row relaxations of an MIP. Recently, there has been a significant amount of work devoted to these so-called *multirow Gomory cuts*. The idea is to extend the fact that GMI cuts are, among the cyclic group cuts, the ones that have the best coefficients for the continuous variables. Indeed, Dash and Günlük [68] observe that this is one of the reasons why GMI cuts are (computationally) the most important cuts among all cyclic group cuts. The extension of such an idea to multiple rows is to consider a tableau of the linear programming relaxation of an

IP, derive the cuts with the best coefficients for the continuous variables, and lift back the integer variables.

To achieve this goal, we follow the same steps that were developed in the section titled “Gomory Cuts as Group Cuts” to obtain the corner and group relaxations. If we now consider Equation (30) and further drop all integrality constraints from x_N and the non-negativity constraints for x_B , we get the following set:

$$\left\{ x : \begin{array}{l} f + \sum_{j \in N} r^j x_j \in \mathbb{Z}^m \\ x_N \geq 0. \end{array} \right\}. \quad (31)$$

So if we obtain a facet-defining inequality for Equation (31) and then lift the integer variables back to obtain an inequality for Equation (30), then we get an inequality with good coefficients for any continuous variable, thereby emulating the same property that GMI cuts have in the case $m = 1$.

Andersen *et al.* [78] show that facet-defining inequalities for Equation (31) when $m = 2$ are intersection cuts and are related to lattice-free convex sets. Borozan and Cornuéjols [79] show that minimal inequalities for a semiinfinite extension of Equation (31) obtained by adding one variable for all possible real coefficients $r^j \in \mathbb{R}^m$ correspond to maximal lattice-free convex sets. Cornuéjols and Margot [80] study which of these inequalities define facets of Equation (31), while the papers [81–83] study the lifting of the integer variables to obtain cuts valid for Equation (30). Other recent papers related to multirow Gomory cuts are Refs 84, 85.

Extensions of multirow Gomory cuts are studied in Refs 86–88 by considering tighter relaxations than Equation (31) and its semiinfinite extension. In addition, the papers [89,90] show computational experiments with multirow Gomory cuts and there are several other groups performing computational experiments as well. Finally, the papers [91,92] study the GMI rank of the multirow Gomory cuts. One particularly interesting result is that some of these cuts have an infinite GMI rank, thereby showing

that a lot can be gained by using these cuts in addition to GMI cuts.

Summing up, this is one particular area of research that is very recent and very active. Indeed the earliest of the 15 papers cited above is dated 2007 and we know of several different research groups actively researching questions related to multirow Gomory cuts.

CONCLUSION

In this article, we tried to do a very brief review of Gomory cuts, trying to be at the same time thorough and concise to fit into the allowed space. While this topic is as old as the field of integer programming, this remains a very active research topic, with much research still being carried out today. We hope that we have been able to provide a glimpse into the topic, stating the main results and with enough references so that the interested reader can explore further.

INTRODUCTION

This article reviews gradient-type descent methods for the unconstrained minimization problem:

$$\min \{f(x) : x \in \mathbb{R}^n\}, \quad (1)$$

where $f: \mathbb{R}^n \rightarrow \mathbb{R}$. We first focus on the *gradient method* for differentiable functions and then briefly discuss the analogous *subgradient method* for nondifferentiable convex functions. The gradient method, which is also called the *method of steepest descent*, was proposed by Cauchy in 1847 [1] for solving systems of equations. This algorithm is one of the most fundamental and simple derivative-based procedures for unconstrained minimization of a differentiable function. The performance of the method in terms of speed of convergence is lacking, and it tends to suffer from very slow convergence especially as a stationary point is approached. However, it does guarantee global convergence under reasonable conditions, and admits a thorough mathematical analysis of its behavior. For this reason, the gradient method has been used as a starting point in the development of more sophisticated globally convergent algorithms with better convergence properties for unconstrained minimization. Numerous excellent books [2–11] already cover this topic in varying amounts of detail. Our goal here is to present a cogent overview of this fundamental method and consolidate the treatment

of this topic in various books and the general body of nonlinear programming literature.

THE GRADIENT METHOD

We review some basic definitions and properties before discussing the gradient method in detail.

Definition 1. A nonzero direction d is called a *descent direction* at $\bar{x}$ if $f(\bar{x} + \lambda d) < f(\bar{x})$ for all $\lambda \in (0, \delta)$ for some $\delta > 0$.

Definition 2. Consider a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$, the directional derivative of f at $\bar{x}$ along a nonzero direction d denoted by $f'(\bar{x}, d)$, is given by the following limit if it exists, which reduces to the inner product whenever the gradient exists

$$f'(\bar{x}, d) = \lim_{\lambda \downarrow 0} \frac{f(\bar{x} + \lambda d) - f(\bar{x})}{\lambda} = \nabla f(\bar{x})^t d. \quad (2)$$

If $f'(\bar{x}, d) < 0$ then d is a descent direction at $\bar{x}$. Given a differentiable function f , the gradient method in each step, moves along the direction that minimizes $f'(\bar{x}, d)$, that is, the direction of steepest descent. The method stops when such a move is not possible.

Proposition 1. If a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is differentiable at $\bar{x}$ and $\nabla f(\bar{x}) \neq \mathbf{0}$ then $\bar{d} = -\nabla f(\bar{x}) / \|\nabla f(\bar{x})\|$ minimizes $f'(\bar{x}, d)$ subject to $\|d\| \leq 1$.

Proposition 2. Suppose $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is differentiable at $\bar{x}$. If $\bar{x}$ is a local minimum, $\nabla f(\bar{x}) = \mathbf{0}$.

Hence, whenever the gradient is nonzero, $-\nabla f(\bar{x})$ gives us the direction of steepest descent at $\bar{x}$. When it is zero, the method has reached a *stationary point*, which is a necessary condition for optimality. Further note that when $\nabla f(\bar{x}) = \mathbf{0}$, $f'(\bar{x}, d) = 0$ for all d . However, it is possible for descent directions of f to exist at $\bar{x}$.

Gradient Method with Exact Line Searches

Given a point $\bar{x}$, the gradient method conducts a line search at $\bar{x}$ along the direction $-\nabla f(\bar{x})/\|\nabla f(\bar{x})\|$ or equivalently along $-\nabla f(\bar{x})$ to find the next point. This step is repeated until some appropriate termination condition is satisfied. Algorithm 1 describes the gradient method. Theorem 1 addresses the convergence of the gradient method.

Algorithm 1. The Gradient Method.

- 1: **Initialization.** Select a starting point x^0 , the termination tolerance $\epsilon > 0$ and let $k = 0$
- 2: **while** $\|\nabla f(x^k)\| > \epsilon$ **do**
- 3: $\lambda_k \leftarrow \operatorname{argmin} \{f(x^k - \lambda \nabla f(x^k)) : \lambda \geq 0\}$
- 4: $x^{k+1} = x^k - \lambda_k \nabla f(x^k)$
- 5: $k \leftarrow k + 1$
- 6: **end while**

Exact line search guarantees descent in the function value and it can also be verified that two consecutive search directions are orthogonal to each other. Since λ_k minimizes $\phi_k(\lambda) = f(x^k - \lambda \nabla f(x^k))$ over $\lambda \geq 0$ and $-\nabla f(x^k) \neq \mathbf{0}$ is a descent direction (i.e., $\lambda_k > 0$), we must have $\phi'_k(\lambda_k) = 0$, or

$$\begin{aligned} \frac{df(x^k - \lambda \nabla f(x^k))}{d\lambda} \Big|_{\lambda=\lambda_k} \\ = -\nabla f(x^{k+1})^t \nabla f(x^k) = 0. \end{aligned} \quad (3)$$

Theorem 1 [3]. Consider the unconstrained minimization of a continuously differentiable function $f: \mathbb{R}^n \rightarrow \mathbb{R}$. Assume that the sequence $\{x^k : k \geq 0\}$ generated by the gradient method described in Algorithm 1 is contained in a compact set. Then every limit point of the sequence $\{x^k : k \geq 0\}$ is a stationary point.

The gradient method with exact line search is globally convergent under the stated assumptions of Theorem 1. The next relevant question deals with the speed of convergence of the gradient method, the analysis of which focuses on convex quadratic and nonquadratic functions. Consider first the convex quadratic case, $f(x) = \frac{1}{2}x^t Qx$, where

Q is symmetric positive definite. Clearly, the global minimum is $\mathbf{0}$ and $f(\mathbf{0}) = 0$. Note that the analysis of the gradient method for convex quadratic functions is very important for understanding the behavior of the method near the local minimum of any twice differentiable function.

Theorem 2 [3]. Suppose the gradient method described in Algorithm 1 is applied to $f(x) = \frac{1}{2}x^t Qx$, then the following inequality holds.

$$\frac{f(x^{k+1})}{f(x^k)} \leq \left(\frac{\rho - 1}{\rho + 1} \right)^2, \quad k = 0, 1, 2, \dots, \quad (4)$$

where ρ is the condition number of Q .

We can see from Theorem 2, the sequence $\{f(x^k) : k \geq 0\}$ converges to 0 at least linearly. When the condition number is 1, we have convergence in a single step as observed when $f(x) = \frac{1}{2}(x^t x)$. When the condition number is much larger than 1, we say the problem is *ill-conditioned* and the speed of convergence is rather slow. The latter case gives rise to the phenomenon of “zigzagging” that is illustrated in Fig. 1 for a two-dimensional problem with long, narrow level sets. The poor convergence of the gradient method in such cases can be intuitively explained as follows.

The gradient method only utilizes first-order information about the function in determining the direction of movement. It uses the linear approximation of f ,

$$\begin{aligned} f(x^k + \lambda d) &= f(x^k) + \lambda \nabla f(x^k)^t d \\ &\quad + \lambda \|d\| \alpha(x^k; \lambda d), \end{aligned} \quad (5)$$

in which the term $\lambda \|d\| \alpha(x^k; \lambda d)$ is ignored. Close to the stationary point, when $\|\nabla f(x^k)\|$ is almost zero, the term $\lambda \nabla f(x^k)^t d$ is small. Now even for small values of λ , the term $\lambda \|d\| \alpha(x^k; \lambda d)$ may contribute significantly to the description of f . So moving along the directions generated as we approach a stationary point does not effectively decrease the objective function value [2].

Figure 1. The progress of the gradient method for minimizing $f(x_1, x_2) = (1/2)(x_1^2 + 20x_2^2)$. The minimizing point is $(0, 0)$ and the starting point is $(-4.5, -0.5)$.

Before concluding this section, we provide an extension of Theorem 2 to certain strongly convex functions. Function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is said to be *strongly convex* if there exists $m > 0$ such that $\nabla^2 f(x) \geq mI$ for all $x \in \mathbb{R}^n$, where $A \geq B$ means that $A - B$ is positive semidefinite. Note that by Taylor's theorem, for any $x, y \in \mathbb{R}^n$ there exists z on the line segment joining x, y such that

$$f(y) = f(x) + \nabla f(x)^t(y - x) + \frac{1}{2}(y - x)^t \nabla^2 f(z)(y - x). \quad (6)$$

In addition, if f is strongly convex, we obtain

$$f(y) \geq f(x) + \nabla f(x)^t(y - x) + \frac{m}{2}(\|y - x\|)^2, \quad (7)$$

which is stronger than the basic supporting hyperplane inequality that characterizes differentiable convex functions (obtained by setting $m = 0$). In particular, this implies that the sublevel sets of f are bounded and hence, the set $\{x \in \mathbb{R}^n : f(x) \leq f(x^0)\}$ is

bounded. Further, $\min\{f(x) : x \in \mathbb{R}^n\}$ has a unique minimum x^* since f is strictly convex.

Theorem 3 [3]. Suppose f is twice continuously differentiable and its Hessian satisfies the condition,

$$mI \leq \nabla^2 f(x) \leq MI, \quad \forall x \in \mathbb{R}^n, \quad (8)$$

where $0 < m \leq M$. Then, for every x^0 the sequence $\{x^k : k \geq 0\}$ generated by the gradient method described in Algorithm 1 satisfies

$$\limsup_{k \rightarrow \infty} \frac{f(x^{k+1}) - f(x^*)}{f(x^k) - f(x^*)} \leq \left(\frac{\rho - 1}{\rho + 1} \right)^2, \quad (9)$$

where ρ is the condition number of $\nabla^2 f(x^*)$ and x^* is the unique global minimum.

Similar to Theorem 2 for convex quadratics, Theorem 3 shows that the sequence $\{f(x^k) : k \geq 0\}$ converges to $f(x^*)$ at least linearly. The ill-conditioning effects are also explained by this result.

Gradient Method with Inexact Line Searches

Performing exact line searches is often computationally impractical due to the excessive function evaluations required. The descent property guaranteed by exact line search, however, is important for the convergence of the algorithm. Alternatives to exact line search that still preserve descent and global convergence are important issues in this context. The gradient method can be implemented with a constant step size $\tau > 0$ as

$$x^{k+1} = x^k - \tau \nabla f(x^k), \quad k = 0, 1, 2, \dots \quad (10)$$

Under certain conditions, this approach can also be shown to be convergent.

Theorem 4 [3]. *Assume that the function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is continuously differentiable and its gradient is Lipschitz continuous with the Lipschitz constant $L > 0$. Further assume that the function f is bounded from below*

and the set $\{x \in \mathbb{R}^n : f(x) \leq f(x^0)\}$ is bounded. If the step size τ satisfies $0 < \tau < \frac{1}{L}$, then the sequence $\{x^k : k \geq 0\}$ generated using Equation (10) is bounded and every limit point of this sequence is a stationary point.

While the convergence of the gradient method with constant step size is interesting, it requires knowledge of the Lipschitz constant L which is a considerable drawback. A more attractive alternative is the use of Armijo's rule to conduct an inexact line search. We conclude this section with the gradient method that uses Armijo's inexact line search described in Algorithm 2. Theorem 5 establishes global convergence of the algorithm with Armijo's inexact line search. Note that this algorithm is better suited to computer implementation for any differentiable function even though convergence guarantee requires Lipschitz continuity among other conditions.

Algorithm 2. The gradient method with Armijo's line search.

```

1: Initialization. Select a starting point  $x^0$ , the termination tolerance  $\epsilon > 0$ , fixed step
   length parameter  $\bar{\lambda} \in (0, \infty)$ , line search parameters  $\alpha \in (1, \infty)$  and  $\beta \in (0, 1)$  and let  $k = 0$ 
2: while  $\|\nabla f(x^k)\| > \epsilon$  do
3:   Define line search function  $\phi(\lambda) = f(x^k - \lambda \nabla f(x^k))$  for  $\lambda \geq 0$ 
4:   Define Armijo's function  $\hat{\phi}(\lambda) = \phi(0) + \lambda \beta \phi'(0)$  for  $\lambda \geq 0$ 
5:   if  $\phi(\bar{\lambda}) \leq \hat{\phi}(\bar{\lambda})$  then
6:     Find the largest integer  $t \geq 0$  such that  $\phi(\alpha^t \bar{\lambda}) \leq \hat{\phi}(\alpha^t \bar{\lambda})$ 
7:      $\lambda_k = \alpha^t \bar{\lambda}$ 
8:   else
9:     Find the smallest integer  $t \geq 1$  such that  $\phi(\alpha^{-t} \bar{\lambda}) \leq \hat{\phi}(\alpha^{-t} \bar{\lambda})$ 
10:     $\lambda_k = \alpha^{-t} \bar{\lambda}$ 
11:   end if
12:    $x^{k+1} = x^k - \lambda_k \nabla f(x^k)$ 
13:    $k \leftarrow k + 1$ 
14: end while

```

Theorem 5 [2]. *Assume that the function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is continuously differentiable and its gradient is Lipschitz continuous with Lipschitz constant $L > 0$ on the set $\{x \in \mathbb{R}^n : f(x) \leq f(x^0)\}$. Suppose Algorithm 2 generates the sequence $\{x^k : k \geq 0\}$, then $\lim_{k \rightarrow \infty} \nabla f(x^k) = 0$. In addition, if the set $\{x \in \mathbb{R}^n : f(x) \leq f(x^0)\}$ is bounded, then every limit point of the sequence $\{x^k : k \geq 0\}$ is a stationary point.*

SUBGRADIENT METHOD FOR CONVEX FUNCTIONS

Consider the unconstrained minimization problem (1), in which function f is convex but not necessarily differentiable. A natural analog of the gradient method employs subgradients of the function in place of gradients. However, not all properties of the

gradient method such as descent in each iteration can be guaranteed. Nonetheless, globally convergent subgradient methods can be developed based on some interesting observations.

Definition 3. Let $f : \mathbb{R}^n \rightarrow \mathbb{R}$ be a convex function. Then $\eta \in \mathbb{R}^n$ is called a *subgradient* of f at $\bar{x}$ if the following condition holds:

$$f(x) \geq f(\bar{x}) + \eta^t(x - \bar{x}) \quad \forall x \in \mathbb{R}^n. \quad (11)$$

The collection of all subgradients at $\bar{x}$ is called the *subdifferential* of f at $\bar{x}$ denoted by $\partial f(\bar{x})$. If f is differentiable at $\bar{x}$, then $\partial f(\bar{x}) = \{\nabla f(\bar{x})\}$, the singleton set.

Proposition 3. Let $f : \mathbb{R}^n \rightarrow \mathbb{R}$ be a convex function. Consider the problem $\min\{f(x) : x \in \mathbb{R}^n\}$. The point $\bar{x} \in \mathbb{R}^n$ is an optimal solution to this problem if and only if $\mathbf{0} \in \partial f(\bar{x})$.

Descent in the function value in each iteration is a key requirement for showing convergence of the gradient method under various settings. It is important to note that $\eta \in \partial f(\bar{x})$, $\eta \neq \mathbf{0}$ need not be a descent direction of f at $\bar{x}$. The negative of the subgradient of minimum norm when it is different from $\mathbf{0}$ is the direction of steepest descent. Furthermore,

Algorithm 3. The subgradient method.

```

1: Initialization. Select a starting point  $x^0$ , the termination tolerance  $\epsilon > 0$ , and let  $k = 0$ 
2:  $UB_k \leftarrow f(x^k)$ , incumbent solution  $x^* \leftarrow x^0$ 
3: Find a subgradient  $g^k \in \partial f(x^k)$  of  $f$  at  $x^k$ 
4: if  $g^k = \mathbf{0}$  then
5:   Stop and return  $x^k$  as the solution
6: else
7:   Let  $d^k = -g^k / \|g^k\|$ , select a step size  $\lambda_k > 0$ 
8:    $x^{k+1} \leftarrow x^k + \lambda_k d^k$ 
9:   if  $f(x^{k+1}) < UB_k$  then
10:     $UB_{k+1} \leftarrow f(x^{k+1})$  and  $x^* \leftarrow x^{k+1}$ 
11:   else
12:     $UB_{k+1} \leftarrow UB_k$ 
13:   end if
14:    $k \leftarrow k + 1$ 
15:   Go to Step 3
16: end if
```

Since Algorithm 3 selects $g^k \in \partial f(x^k)$ arbitrarily, even for some k , $\mathbf{0} \in \partial f(x^k)$, the termination condition $g^k = \mathbf{0}$ may not be achieved. Other practical termination criteria that

even if $\bar{x}$ is optimal, we may fail to detect that $\mathbf{0} \in \partial f(\bar{x})$. Hence, employing a line search along the negative of the subgradient in each iteration is not well motivated. However, from the definition of a subgradient we have

$$\{x : f(x) \leq f(\bar{x})\} \subseteq \{x \in \mathbb{R}^n : \eta^t(x - \bar{x}) \leq 0\}. \quad (12)$$

Hence, taking a step along the negative of the subgradient intuitively takes us “closer” to the optimal point. In fact, if a step of prescribed length is taken along the negative of the subgradient in each iteration, the method can be shown to converge.

Subgradient Method and Convergence

Given an iterate x^k , positive step size λ_k and a subgradient of f at x^k , $g^k \in \partial f(x^k)$, the next iterate x^{k+1} is constructed using the following relationship:

$$x^{k+1} = x^k + \lambda_k d^k, \quad (13)$$

where $d^k = -g^k / \|g^k\|$ is the direction of movement. The scaling coefficient $\|g^k\|$ in d^k can be replaced by $\max(c, \|g^k\|)$ or $\max(c, \|g^k\|^2)$ where $c > 0$ is a fixed constant [3].

limit the maximum number of iterations, or terminate when $\|x^{k+1} - x^k\| < \epsilon$ or $\|x^{k+1} - x^k\| / \|x^k\| < \epsilon$ for a sufficiently small $\epsilon > 0$, can be used. Theorem 6 addresses the

convergence of the subgradient method which can be guaranteed if the step sizes satisfy certain conditions.

Theorem 6 [2,3]. *Suppose f is convex and assume an optimal solution to problem (1) exists. Suppose the subgradient algorithm 3 is used to solve this problem and assume the nonnegative step size λ_k satisfies the following conditions:*

$$\{\lambda_k\} \rightarrow 0^+, \quad (14)$$

$$\sum_{k=0}^{\infty} \lambda_k = \infty. \quad (15)$$

Then, either the algorithm terminates finitely with an optimal solution, or the sequence $\{UB_k : k \geq 0\}$ generated by the subgradient method satisfies

$$\{UB_k\} \rightarrow f^* = \min \{f(x) : x \in \mathbb{R}^n\}. \quad (16)$$

Observe that sequence $\{f(x^k) : k \geq 0\}$ is generally nonmonotone, and we have effectively shown in Theorem 6 that $\liminf_{k \rightarrow \infty} f(x^k) = f^*$. Under stronger conditions, even the convergence of $\{x^k : k \geq 0\}$ can be established.

Theorem 7 [2,3]. *Suppose f is convex and assume an optimal solution to problem (1) exists. Suppose the subgradient algorithm 3 is used to solve this problem and assume the nonnegative step size λ_k satisfies the following conditions:*

$$\sum_{k=0}^{\infty} \lambda_k = \infty, \quad (17)$$

$$\sum_{k=0}^{\infty} \lambda_k^2 < \infty. \quad (18)$$

Then, either the algorithm terminates finitely with an optimal solution, or the sequence $\{x^k : k \geq 0\}$ generated by the subgradient method converges to an optimal solution of Equation (1).

Conditions of Theorem 6 on selecting step sizes guarantees convergence of the subgradient method. But in practice, these

conditions necessarily do not result in the algorithm's convergence. For example, selecting $\lambda = 1/k$ satisfying conditions of Theorem 6 as well as Theorem 7 has been observed to be unsatisfactory in practice [2,3]. Hence, the choice of step length is important and nontrivial. Better insight into the feature of the subgradient method that drives convergence can be gained by carefully exploring the intuition presented by Equation (12). Let x^* be an optimal solution to the problem (1) and x^k be a nonoptimal iterate obtained from the algorithm. Since f is convex, $f(x^*) \geq f(x^k) + (x^* - x^k)^t g^k$ which results in $(x^* - x^k)^t (-g^k) \geq f(x^k) - f(x^*) > 0$. Hence, direction $d^k = -g^k / \|g^k\|$, even when not a descent direction, leads to a point which is closer to x^* in Euclidean norm than x^k . This fundamental fact facilitates convergence of the subgradient method. From this point of view, an ideal step size is one which takes us closest to x^* . In the other words, this ideal step size is the one which makes $x^{k+1} - x^*$ orthogonal to d^k . So we require λ_k^* to satisfy

$$\lambda_k^* = (x^k - x^*)^t g^k / \|g^k\|, \quad (19)$$

which needs to be approximated as x^* is unknown. Since f is convex, $f(x^*) \geq f(x^k) + (x^* - x^k)^t g^k$. Using Equation (19), we have $\lambda_k^* \geq (f(x^k) - f(x^*)) / \|g^k\|$. The step size can then be chosen using the following equation:

$$\lambda_k = \beta_k (f(x^k) - \underline{f}) / \|g^k\|, \quad (20)$$

where $\underline{f}$ is a lower bound on $f(x^*)$ and $\beta_k > 0$. By selecting $\epsilon_1 < \beta_k \leq 2 - \epsilon_2, \forall k$ for some $\epsilon_1, \epsilon_2 > 0$ and using $f(x^*)$ instead of $\underline{f}$, the sequence $\{x^k : k \geq 0\}$ generated by the subgradient algorithm can be shown to converge to x^* [2]. Practical implementations of this method based on Equation (20) employ what is called the *block halving scheme*. For more details on this scheme, the reader is referred to Bazaraa *et al.* [2]. Interested readers can find fundamental results on nondifferentiable optimization in Shor [12]. A recent survey of nondifferentiable optimization algorithms such as the subgradient method, the subgradient method with space

dilation, and the r -algorithm can be found in Shor [13].

CONCLUSION

As it can be observed from Theorems 1, 4, and 5, the global convergence of the gradient method is quite impressive. However, it is offset by its typically slow convergence as observed from Theorems 2 and 3 even for convex minimization. Despite its drawbacks, applications of the gradient method can be found in training neural networks [14], for solving a system of nonlinear equations by solving the sum of squares expression [15], for solving a system of fuzzy linear equations [16], and in multicriteria optimization [17,18]. The gradient method is used to solve 0,1-nonlinear programs by transforming them to an unconstrained optimization problem in Anjidani and Effati [19]. The gradient method with affine scaling is developed for linear programming in Gonzaga [20]. The notion of steepest descent among other classical approaches is used to develop the gravitational method for linear programming in Chang and Murty [21].

Some of the most competitive globally convergent algorithms for unconstrained minimization of differentiable functions can be viewed as extensions of the gradient method that modify the direction of search in a manner that accelerates convergence. Pure Newton method (see **Newton-Type Methods**) converges rapidly when started close to the solution, but does not provide global convergence. A common approach to overcome the poor convergence of gradient method is to deflect the gradient akin to gradient deflection by the inverse of the Hessian matrix used in Newton's method. In this approach, rather than using the direction $d = -\nabla f(x)$, we use direction $d = -D\nabla f(x)$ giving rise to quasi Newton methods (see **Quasi-Newton Methods**), or $d = -\nabla f(x) + g$ giving rise to conjugate gradient methods (see **Nonlinear Conjugate Gradient Methods**). By virtue of its simplicity and amenability to mathematical analysis, the gradient method will remain central to the study of algorithms for nonlinear optimization.

GRAPH SEARCH TECHNIQUES

INTRODUCTION

Graph searching problems serve as mathematical models for many real-world problems, such as capturing a robber in a building, clearing a complex system of interconnected pipes which is contaminated by some noxious gas, or killing a computer virus in a network system. The meaning of a cleared or contaminated edge varies with problems. For example, in the problem of capturing robbers, a cleared edge means that there is no robber hiding along this edge, while a contaminated edge means that a robber may be hiding along this edge. Knowing that our goal is to clear a graph (capture all robbers), a basic question is what is the fewest number of searchers required? We call this the *search number*. There are many graph searching problems motivated by applied problems or inspired by some theoretical issues in computer science and discrete mathematics. These problems are defined by the class of graphs (e.g., undirected graphs, digraphs, or hypergraphs), the actions of searchers and robbers, conditions of captures, speed, visibility, and so on.

A large number of graph searching models have been introduced. We will focus on some basic models. The reader is referred to survey papers [1–3] for a more thorough exposition of graph searching problems. Graph searching has a variety of names in the literature, such as cops-and-robber games and pursuit-evasion problems. In some problems, searchers are also called cops, sweepers, or pursuers, and robbers are called intruders, fugitives, or evaders.

All graphs and digraphs in this article are finite. We use $G = (V, E)$ ($D = (V, E)$) to denote a graph (digraph) with vertex set V and edge set E . We use uv to denote an edge in a graph with two end vertices u and v and (u, v) to denote a directed edge in a digraph with tail u and head v .

This article surveys graph searching problems on undirected graphs and digraphs. There are three major parts of the survey. The first part deals with the undirected graph searching problems in which the robber can move at very large speed. The second part deals with the digraph searching problems in which searchers and the robber may or may not obey the edge directions. The third part deals with the cops-and-robber games in which cops and the robber take turns to move.

SEARCHING UNDIRECTED GRAPHS

The first graph searching model was introduced by Parsons [4], after being approached by Breisch [5] (a paper dealing with finding a spelunker lost in a system of caves). Let G be a connected, undirected, finite graph embedded in $\mathbb{E}^3$ (i.e., $\mathbb{R}^3$ with the Euclidean distance metric) such that no pair of edges intersect at a point that is not a common endpoint. A point in G is either a vertex or an interior point of an edge in G . Imagine there is a robber in G who can be located at any point of G , that is, anywhere along an edge or at a vertex. We want to capture the robber using the minimum number of searchers. For each positive integer k , let $C_k(G)$ be the set of all families $F = \{f_1, f_2, \dots, f_k\}$ of continuous functions $f_i : [0, \infty) \rightarrow G$. A continuous search strategy for G is a family $F \in C_k(G)$ such that for every continuous function $h : [0, \infty) \rightarrow G$ (corresponding to the robber), there is a $t_h \in [0, \infty)$ and $f_i \in F$ satisfying $h(t_h) = f_i(t_h)$. We say that f_i captures the robber at time t_h . The continuous search number of a graph G is the smallest k such that there exists a search strategy for G in $C_k(G)$.

There are some contexts for which Parsons searching is the model required. For example, in the case of searching for someone lost or a robber hiding in a cave system, the robber and the searchers move continuously. But the notion of Parsons searching presents certain difficulties because the model involves the action of continuous functions defined on the nonnegative real numbers.

There are three basic discrete versions of Parsons searching: edge searching, node searching, and mixed searching, which involves placing some restriction on searchers, but placing no restrictions on a robber. In these search models, the discrete time intervals are introduced. The basic idea is that for each time interval, only one searcher can have one of the three actions: placing, removing, and sliding. Initially, G contains a robber who is located at a point in G , and G does not contain any searchers. Each searcher has no information on the whereabouts of the robber (invisible), but the robber has complete knowledge of the location of all searchers. The goal of the searchers is to capture the robber, and the goal of the robber is to avoid being captured. The robber always chooses the best strategy so that he evades capture. Suppose we start at time t_0 and the robber is captured at time t_N , and the search time is divided into N intervals $(t_0, t_1]$, $(t_1, t_2]$, ..., $(t_{N-1}, t_N]$ such that in each interval $(t_i, t_{i+1}]$ (also called *step*) exactly one searcher performs one action. The robber can move from a point x to a point y in G at any time in the interval (t_0, t_N) if there exists a path between x and y which contains no searcher. In the *edge search model* introduced by Megiddo *et al.* [6], there are three actions for searchers: placing a searcher on a vertex, removing a searcher from a vertex, and sliding a searcher along an edge from one end to the other. The robber is captured if a searcher and the robber occupy the same point on G . In the *node search model* introduced by Kirousis and Papadimitriou [7], there are two actions for searchers: placing a searcher on a vertex and removing a searcher from a vertex. The robber is captured if a searcher and the robber occupy the same vertex of G or the robber is on an edge whose endpoints

are both occupied by searchers. In the *mixed search model* introduced by Bienstock and Seymour [8], searchers have the same actions as those in the edge search model. The robber is captured if a searcher and the robber occupy the same point on G or the robber is on an edge whose endpoints are both occupied by searchers.

The edge search number of G , denoted by $es(G)$, is the smallest positive integer k such that k searchers can capture the robber. Similarly, we can define the node search number of G ($ns(G)$), and mixed search number of G ($ms(G)$). The following relationships between search numbers are given in Refs 7 and 8: $ns(G) - 1 \leq es(G) \leq ns(G) + 1$; $ms(G) \leq es(G) \leq ms(G) + 1$; and $ms(G) \leq ns(G) \leq ms(G) + 1$.

Megiddo *et al.* [6] showed that the edge search problem is NP-hard. This problem also belongs to the NP class. This follows from the monotonicity result of LaPaugh [9], in which she showed that recontamination of edges cannot reduce the number of searchers needed to clear a graph. A search strategy is monotonic if the set of cleared edges before any step is always a subset of the set of cleared edges after the step. Monotonicity is a very important issue in graph search problems. Bienstock and Seymour [8] proposed a method that gives a succinct proof for the monotonicity of the mixed search problem, which implies the monotonicity of the edge search problem and the node search problem. Fomin and Thilikos [10] provided a general framework that can unify monotonicity results in a unique minmax theorem.

Search numbers have close relationships with pathwidth and treewidth [11,12]. Given a graph $G = (V, E)$, a tree decomposition of G is a pair (T, W) with a tree $T = (I, F)$, $I = \{1, 2, \dots, m\}$, and a family of nonempty subsets $W = \{W_i \subseteq V : i = 1, 2, \dots, m\}$, such that

1. $\bigcup_{i=1}^m W_i = V$;
2. for each edge $uv \in E$, there is an $i \in I$ with $\{u, v\} \subseteq W_i$; and
3. for all $i, j, k \in I$, if j is on the path from i to k in T , then $W_i \cap W_k \subseteq W_j$.

The width of a tree decomposition (T, W) is $\max\{|W_i| - 1 : 1 \leq i \leq m\}$. The *treewidth* of G , denoted by $\text{tw}(G)$, is the minimum width over all tree decompositions of G . A tree decomposition (T, W) is a path decomposition if T is a path; the *pathwidth* of a graph G , denoted by $\text{pw}(G)$, is the minimum width over all path decompositions of G .

Another related graph parameter is the vertex separation introduced by Ellis *et al.* [13]. The following relationships are given in Kinnersley [14], Kirousis and Papadimitriou [7], and Yang [15] : $\text{sms}(G) = \text{pw}(G) = \text{vs}(G) = \text{ns}(G) - 1$, where $\text{sms}(G)$ is the strong-mixed search number of G introduced in Yang [15] and $\text{vs}(G)$ is the vertex separation of G .

Dendris *et al.* [16] introduced the *inert-robber game*, which has the same setting as the node searching model except that the robber stays only on vertices and moves just before a searcher is going to be placed on the vertex v currently occupied by the robber (given that there is a vertex u that can be reached via a searcher-free path from v to u ; otherwise the robber is captured). They showed that the inert-robber game is monotonic and the search number of a graph in the inert-robber game is equal to the treewidth of the graph plus one.

Seymour and Thomas [17] introduced another variant of graph searching, *visible-robber game*. Its setting differs from node search in that the robber stands only on vertices and is visible to searchers. They showed that the visible-robber game is monotonic and the search number of a graph in the visible-robber game is equal to the treewidth of the graph plus one. They also showed that if there is a nonlosing strategy for the robber, then there is a nice nonlosing strategy with a particularly simple form.

The problem of determining whether k searchers can capture the robber in the visible-robber game (or inert-robber game) is NP-complete because it is monotonic and determining treewidth is NP-complete [18].

There are many variants of graph searching models, for example, connected search [19,20], domination search [21], and robber-and-marshals games [22].

SEARCHING DIGRAPHS

Johnson *et al.* [23] generalized the concept of treewidth to digraphs. For a digraph $D = (V, E)$, let Z and S be two disjoint subsets of V . S is Z -normal if for every directed path, $v_1 \dots v_k$, in D such that $v_1, v_k \in S$, either $v_i \in S$ for all $1 \leq i \leq k$, or there exists $j \leq k$ such that $v_j \in Z$. Given a directed tree T with edges oriented away from a unique vertex $r \in V(T)$ (called the *root*), we write $t > e$ for $t \in V(T)$ and $e \in E(T)$ if e occurs on the unique directed path from r to t , and $e \sim t$ if e is incident with t . An arboreal decomposition of a digraph D is a triple (T, X, W) where T is a directed tree with a unique root, and $X = \{X_t \subseteq V : t \in V(T)\}$ and $W = \{W_e \subseteq V : e \in E(T)\}$ satisfy the following:

- X is a partition of V into nonempty sets.
- If $e \in E(T)$, then $\bigcup\{X_t : t \in V(T) \text{ and } t > e\}$ is W_e -normal.

The width of an arboreal decomposition (T, X, W) is the minimum k such that for all $t \in V(T)$, $|X_t \cup \bigcup_{e \sim t} W_e| \leq k + 1$. The *directed treewidth* of D is the least integer k such that D has an arboreal decomposition of width k . Johnson *et al.* [23] introduced a generalization of the visible-robber game, called the *strong directed visible-robber game*. In the strong directed visible-robber game, the searchers and robber occupy only vertices and must obey the edge directions when they move along edges. The searchers have two actions—placing and removing. The robber is visible, and the robber can move from vertex u to v if there is a searcher-free directed cycle containing u and v . Let $k \geq 1$ be an integer. A *haven* of order k in a digraph D is a function β assigning to every $Z \subseteq V(D)$ with $|Z| < k$ the vertex set of a strong component of $D \setminus Z$ in such a way that if $Z' \subseteq Z \subseteq V(D)$ with $|Z'| < k$, then $\beta(Z) \subseteq \beta(Z')$. If $k - 1$ searchers have a winning strategy on the digraph D , then D has no haven of order k . If β is a haven of order k in D , then the robber wins against $k - 1$ searchers by staying in $\beta(Z)$, where Z is the set of vertices occupied by the searchers. Johnson *et al.* [23] proved that if D has a haven of order k , then its directed treewidth

is at most $3k - 2$. Adler [24] showed that the strong directed visible-robber game is not robber-monotone and when the directed treewidth of D is at least $k - 1$, it is not implied that D has a haven of order k .

Berwanger *et al.* [25] and Obdržálek [26] introduced another complexity measure for digraphs, DAG-width. Given a digraph $D = (V, E)$, a set $X \subseteq V$ guards a set $Y \subseteq V$ if $X \cap Y = \emptyset$ and whenever there is an edge $(u, v) \in E$ such that $u \in Y$ and $v \notin Y$, then $v \in X$. A DAG-decomposition of D is a pair (T, W) with T , an acyclic digraph, and $W = \{W_d \subseteq V : d \in V(T)\}$, a family of nonempty subsets, such that

1. $\bigcup_{d \in V(T)} W_d = V$;
2. for all $d, d', d'' \in V$, if d' is on a directed path from d to d'' in D , then $W_d \cap W_{d''} \subseteq W_{d'}$;
3. for all edges $(d, d') \in E(T)$, $W_d \cap W_{d'}$ guards $W_{\geq d'} \setminus W_d$, where $W_{\geq d'} = \bigcup \{W_{d''} : d'' \in V(T) \text{ and there is a directed path from } d' \text{ to } d'' \text{ in } T\}$; for any root d , $W_{\geq d}$ is guarded by $\emptyset$.

The width of a DAG-decomposition (T, W) is $\max\{|W_d| : d \in V(T)\}$. The DAG-width of D is the minimum width over all DAG-decompositions of D . Corresponding to the DAG-width, Berwanger *et al.* [25] and Obdržálek [26] introduced the *directed visible-robber game*, which has the same setting as the strong directed visible-robber game except that the robber can move from vertex u to v if there is a searcher-free directed path from u to v . They proved that for any digraph D , k searchers have a monotone winning strategy if and only if D has a DAG-decomposition of width k . They also proved that if a graph has DAG-width k , its directed treewidth is at most $3k + 1$. However, there are graphs with directed treewidth 1 and arbitrarily large DAG-width.

Hunter and Kreutzer [27] extended the inert-robber game to the *directed inert-robber game* on digraphs, which has the same setting as the inert-robber game on graphs except that the searchers and robber occupy only vertices and must obey the edge directions when they move along edges. They introduced another complexity measure for

digraphs (Kelly-width), and showed that k searchers have a monotone winning strategy to capture an inert robber in a digraph D if and only if D has Kelly-width k . For the relation between the directed inert-robber game and the directed visible-robber game, if k searchers can capture an inert robber in a digraph D with a robber-monotone strategy, then $2k - 1$ searchers can capture a visible robber in D . For every integer k , there is a digraph such that $3k$ searchers have a robber-monotone winning strategy in the directed inert-robber game but no fewer than $4k$ searchers can capture a visible robber in the directed visible-robber game.

Kreutzer and Ordyniak [28] proved that both directed visible-robber games and directed inert-robber games are nonmonotonic. In particular, within the directed visible-robber game setting, for every $p \geq 2$ there exists a digraph D_p such that the monotonic search number of D_p is $4p - 2$ and the search number of D_p is $3p - 1$. Within the directed inert-robber game setting, for every $p \geq 2$ there exists a digraph D_p such that the monotonic searcher number of D_p is $7p$ and the search number of D_p is $6p$. The problem of determining whether k searchers can capture the robber in the directed visible-robber game (respectively, directed inert-robber game or strong directed visible-robber game) is NP-hard.

Nowakowski [29] and Yang and Cao [30–32] generalized the edge searching problem to digraphs by introducing three digraph search models: directed search, strong search, and weak search. In all three models, the robber is invisible and searchers have three types of actions: placing, removing, and sliding. These models differ in the abilities of the searchers and robber depending on whether or not they must obey the edge directions. In the *directed search* model, both searchers and robber must move in the edge directions; in the *strong search* model, the robber must move in the edge directions but searchers need not; and in the *weak search* model, searchers must move in the edge directions but the robber need not. In particular, in the directed and strong search models, the robber can move from vertex u to vertex v along a searcher-free directed

path from u to v at a great speed at any time; in the weak search model, the robber can move from vertex u to vertex v along a searcher-free undirected path between u and v at a great speed at any time.

For a digraph D , let $ds(D)$, $ss(D)$, and $ws(D)$ denote the directed, strong, and weak search numbers, respectively. Let $es(D)$ be the edge search number of the underlying undirected graph of D . Yang and Cao [30–32] proved that the directed, strong, and weak search problems are all monotonic and NP-complete. They gave the following relationships between search numbers: $ss(D) \leq ds(D) \leq ws(D)$, $ss(D) \leq es(D) \leq ws(D)$, $ds(D) - 1 \leq ss(D) \leq ds(D)$, $ds(D) \leq es(D) + 1$, and $ws(D) \leq es(D) + 2$.

Reed, Seymour, and Thomas introduced the directed pathwidth. Given a digraph $D = (V, E)$, a directed path decomposition of D is a sequence of subsets of vertices $W_1, W_2, \dots, W_m$ such that

1. $\bigcup_{i=1}^m W_i = V$;
2. for $1 \leq i < j < k \leq m$, $W_i \cap W_k \subseteq W_j$;
3. for each edge in D , it either has both endpoints in the same W_i or has its tail in W_i and head in W_j , where $i < j$.

The width of a directed path decomposition of D is $\max_{1 \leq i \leq m} (|W_i| - 1)$. The *directed pathwidth* of D , denoted by $dpw(D)$, is the minimum width over all directed path decompositions of D .

Yang and Cao [33] extended the vertex separation to digraphs. Given a digraph $D = (V, E)$ and a linear layout $L : V \rightarrow \{1, 2, \dots, |V|\}$, let $DV_L(i) = \{x \in V : \text{there exists } y \in V \text{ such that edge } (y, x) \in E \text{ and } L(x) \leq i \text{ and } L(y) > i\}$. The directed vertex separation of D with respect to L , denoted by $dvs_L(D)$, is defined as $dvs_L(D) = \max\{|DV_L(i)| : 1 \leq i \leq |V|\}$. The *directed vertex separation* of D is defined as $dvs(D) = \min\{dvs_L(D) : L \text{ is a linear layout of } D\}$. The following relationships are given in Yang and Cao [33]: $dvs(D) = dpw(D)$, $dvs(G) + 1 \leq ds(G) \leq dvs(G) + 2$, and $dvs(G) \leq ss(G) \leq dvs(G) + 2$.

There are several other searching models on digraphs, such as arc searching [34] and

directed node searching [35]. See also the thesis of Hunter for more discussion [36].

COPS-AND-ROBBER GAMES

A different branch of research on graph searching is the cops-and-robber game, in which cops first locate themselves on the vertices of a graph, and then a robber chooses a vertex; all participants have complete information on the location of all other participants. At even ticks of a clock (starting at 0), some subset of the cops move to adjacent vertices, and, on odd ticks of the clock, the robber moves to an adjacent vertex or stays at his current vertex. Capture takes place when a cop and the robber occupy the same vertex at the same time. This game was introduced by Nowakowski and Winkler [37], and independently by Quilliot [38]. They presented a nice characterization of 1-cop-win graphs. The characterization involves an order relation defined on the vertex set of a graph. We use $N(u)$ to denote the set of all neighbors of u and $N[u] = N(u) \cup \{u\}$. Let $V(G) = \{v_1, v_2, \dots, v_n\}$ and $v \in V(G)$. Define $N_i[v] = N[v] \cap \{v_j : i \leq j \leq n\}$. Nowakowski and Winkler showed that a connected graph is 1-cop-win if and only if its vertices can be linearly ordered $v_1, v_2, \dots, v_n$ such that for each $1 \leq i < n$, there is a j , $i < j \leq n$, satisfying $N_i[v_i] = N_i[v_j]$. A graph is bridged if each of its cycles of length four or more has a shortcut, that is, a pair of vertices whose distance in the graph is shorter than their distance on the cycle. Anstee and Farber [39] gave another characterization of 1-cop-win graphs. They proved that a connected graph is bridged if and only if it is 1-cop-win and contains no induced cycles of length four or five.

The cop number of a graph G , denoted $cn(G)$, is the smallest k such that k cops can capture any robber in the cops-and-robber game. Frankl [40] proved that $cn(G) > d^t$ for a connected graph G with girth at least $8t - 3$ and minimum degree at least $d + 1$. Schroeder [41] showed that for a graph G of orientable genus k , $cn(G) \leq \lfloor \frac{3k}{2} \rfloor + 3$.

Excluding some minors can guarantee a small cop number. Let u be a vertex of a graph

H such that $H - u$ has no isolated vertices. Andreae [42] proved that if G is a graph with no H -minor, then $\text{cn}(G) \leq |E(H - u)|$.

Given a graph containing k cops and one robber, Goldstein and Reingold [43] showed that the problem of determining if k cops can capture a robber from the given initial positions is EXPTIME-complete. For a constant k , they showed that it is polynomial to decide if a graph is k -cop win. Hahn and MacGillivray [44] extended this result by giving a polynomial time algorithm that determines whether k cops can capture l robbers on a graph or digraph, where both k and l are constants.

There are many bounds on cop numbers on different classes of graphs. See Hahn [45] and references therein for details. Several variants of the cops-and-robber game can be found in Clarke and Nowakowski [46,47] and Fomin *et al.* [48].

Graphical methods for reliability analysis have received considerable attention in the literature. In statistical data analysis, graphical techniques are of great importance, as they are very effective and practical tools in summarizing, describing, and presenting data [1–3]. Nowadays, statistical software provide an extensive range of parametric and nonparametric graphical approaches; see, for example, Meeker [4]. Parametric techniques enable model verification, estimation of parameters, and outlier-inlier detection under many statistical distributions such as Weibull, exponential, extreme value, normal, lognormal, and gamma. Although parametric approaches result in high efficiency when underlying distributions are true, assuming a wrong distribution may yield inefficient and misleading results. Nonparametric techniques, which do not require any distributional assumption, generally use empirical functions based on sample observations. Nonparametric techniques are advantageous in the sense that they are simple to carry out and they lead to fast and straightforward summarization of data. On the other hand, they do not make use of distributional structures, which may cause information loss and lack of efficiency, especially for small sample sizes.

In this article, we review some existing nonparametric and parametric graphical methods for reliability data. We first give general definitions and concepts in the area. Then, we discuss some well-known

basic graphical techniques including empirical cumulative distribution function (cdf) plot, hazard plot, probability-probability (P-P) plot, quantile-quantile (Q-Q) plot, the Weibull plot, the Duane plot, mean cumulative function (MCF) plot, and Total Time on Test (TTT) plot. We also describe some problem-specific graphical techniques that explore different applications in the reliability area.

GENERAL OVERVIEW OF GRAPHICAL TECHNIQUES

With the development of technology and industry, more complicated systems have emerged increasing the need for reliability assessment of components and systems. Owing to their easiness of use and practical interpretations, graphical methods have appeared to become one of the most effective assessment tools for analyzing reliability data, starting from the second half of the past century. More emphasis was placed on estimating life distributions and their parameters [1,2,5–10] as well as reliability monitoring through survival curve [11], hazard plotting [12,13–14], the Duane plot [15], and MCF plot [16,17]. For system reliability, see the work by Proctor and Singh [18]. Some other related graphical methods assessing distributional assumptions, such as P-P plotting, were discussed in various works; see, for example, Lawless [19] and Nelson [20]. Besides these, some generalizations of TTT were developed following the initial works by Epstein and Sobel [21] and Barlow and Campo [22]; see Bergman and Klefsjo [23] for details. Toward the end of the past century, the concept of reliability growth models was of much interest to researchers and a number of reliability growth models were proposed to predict and continuously improve the reliability of a component or a system [24–26].

Recent literature mainly revolves around these basic concepts. Many useful variants

of these graphical techniques pertaining to reliability data have been proposed, and new graphical methods have been developed for other practical applications in the field. The succeeding sections summarize these methods and the related literature.

GRAPHICAL TECHNIQUES

Determining Probability Distributions

Many studies in the literature consider parametric graphical approaches to analyze and display reliability data visually. A number of graphical methods have been developed to determine the underlying distributional structure. These easy-to-use methods are summarized in the following sections.

Empirical cdf. Empirical cdf plot is one of the basic and useful tools in examining the behavior of the distribution. One can describe the shape of the sample data by simply plotting the empirical cdf against failure times or lifetimes of components. The theoretical cdf of the hypothesized distribution for the

observations can also be depicted on the same plot to see how well the assumed distribution fits the data. Figure 1 shows an example of an empirical cdf plot (together with the theoretical cdf) of a data set simulated from the Weibull distribution with the cdf,

$$F(x) = P(X \leq x) = 1 - e^{-(x/\sigma)^p} \quad (1)$$

$$x > 0, \sigma > 0, p > 0$$

where σ and p are the scale and the shape parameters, respectively. For more references, see King [27], Lawless [19], Nelson [20], and Abernethy [28].

Probability-Probability (P-P) Plot. The P-P plot is used to check the validity of the assumed distribution. It is obtained by plotting the empirical cdf of data against the specified theoretical cdf. The construction of a P-P plot necessitates that the location and scale parameters of the specified distribution be known. The linearity of the line gives a strong evidence for the validity of the specified distribution; see Wilk and Gnanadesikan [29] and Gnanadesikan [30]. It is also possible

Figure 1. Empirical cdf plot of the simulated data set from Weibull ($\sigma = 2, p = 3$); $n = 100$.

to obtain a P-P plot for censored data as one only needs to plot uncensored observations against their empirical cdf values.

There are many applications and variants of P-P plots in the literature. For example, Chang and Tang [31] studied a simple graphical technique that is analogous to probability plotting for the Birnbaum–Saunders distribution for failure time modeling of fatigue process. They used P-P plot for goodness-of-fit for the Birnbaum–Saunders distribution as well as for the estimation of parameters. See also Wang *et al.* [32] for the use of P-P plot in managing improvements in the strengths of Oriented Strand Board.

Quantile-Quantile (Q-Q) Plot. The Q-Q plot is another type of plot for the verification of the assumed distribution. The horizontal axis consists of the expected values of the standardized order statistics of the assumed distribution and the vertical axis consists of the ordered observations. Figure 2 shows the Q-Q plot of a data set under the assumption of the Weibull distribution with shape parameter 3. The linearity is an evidence of

the true underlying distribution. It should be noted that the shape parameter of the Weibull distribution should be specified to plot the expected values of the standardized distribution ($\sigma = 1$). On the other hand, one does not need to specify the parameters of a location-scale distribution to obtain a Q-Q plot, as they do not affect its linearity.

The Weibull Plot. In the field of reliability, it is quite common to assume Weibull, exponential, extreme value, normal, lognormal, and gamma as the distributions of lifetimes or failure times of components. Among these, especially the Weibull distribution gained a lot of attention in evaluating reliability. Numerous data sets have been analyzed assuming two-parameter Weibull distribution. To assess the validity of a two-parameter Weibull distribution, Weibull plot is often utilized. It is a combination of P-P and Q-Q plots because the graph is obtained by plotting the empirical cdf against the order statistics with scaled axis. For linearity purposes, $\ln[-\ln(1 - F(x))]$ and $\ln x$ can also be used in the axes; see Nelson

Figure 2. Q-Q plot of the simulated data set from Weibull ($\sigma = 2$, $p = 3$); $n = 100$.

Figure 3. Weibull plot of the simulated data set from Weibull ($\sigma = 1, p = 1.5$); $n = 100$.

[20] for more details. Figure 3 shows an example of the Weibull plot obtained from a simulated data with $\sigma = 1$ and $p = 1.5$.

Apart from the classical Weibull plot, Hartler [33] suggested the use of Weibull process plot that works for repairable systems failing according to a Weibull process. Hartler [33] stated that the new graphical method is applicable to preliminary studies of system failure pattern, parameter estimation, early failure detection, failure pattern comparison, and determination of the failure process. In another work by Jiang and Kececioğlu [34], the performances of the two estimation methods based on the Weibull plot for different mixed-Weibull distributions were explored. Using an additive model, Xie and Lai [26] combined two Weibull distributions with decreasing and increasing failure rates to obtain a combined distribution having a bathtub shape. They utilized a simple graphical technique similar to the Weibull plot. The technique is also useful for assessing the goodness-of-fit of the distribution and estimating the unknown

distribution parameters (see also Zhao *et al.* [35] and Zhang and Xie [36]).

ESTIMATING AND MONITORING RELIABILITY

Estimating and monitoring the reliability of components or a system have become quite crucial since it reflects almost all the information about the ongoing process. Many effective graphical tools have been suggested in the literature for various different purposes. These tools are discussed in the following sections.

Hazard Plots

The hazard rate of a component or a system at time t is defined as

$$h(t) = \frac{f(t)}{R(t)}, \quad t > 0, \quad (2)$$

where

$$R(t) = P(X > t) = 1 - F(t), \quad t > 0; \quad (3)$$

Figure 4. Hazard plot of a censored Weibull data set.

$F(t)$ being the cdf. It shows the instantaneous failure rate of a component or a system. The cumulative hazard rate is also often used in reliability analyses and is given by

$$H(t) = \int_0^t h(u)du. \quad (4)$$

Similar to P-P and Q-Q plotting, hazard plotting is a graphical goodness-of-fit method to assess the distributional structure of the data and is obtained by plotting times of failure against the empirical cumulative hazard rates on a log-log scale. Figure 4 shows an example of a hazard plot of a simulated censored Weibull data set having a sample size of 10, 4 of which are censored. The linearity is an evidence for the Weibull distribution.

Numerous papers discussed the use of hazard plotting in the literature. Nelson [14], for example, presented hazard plots for left-truncated lifetime data with illustrations from a real-life data set on compressors in heat pumps. More recently, Persson *et al.* [37] proposed a new method resembling the Kolmogorov–Smirnov method for the comparison of two groups with different hazard functions and conducted a simulation study to compare the effectiveness of six graphical techniques in identifying nonproportionality of hazards. They reported that the Arjas plot

is the best performing one among the six graphical techniques.

The Kaplan–Meier Plot

Graphical techniques are utile for estimating reliability function when the sample is of complete or censored type. The most well-known method of estimating the reliability or survival function is the Kaplan–Meier estimator; see Kaplan and Meier [11] for details. As a graphical tool, the Kaplan–Meier plot is one of the practical and effective graphical techniques in estimating reliability. It is especially advantageous for censored reliability data, as it can handle censored structures. It is obtained by plotting time against the estimated survival function. In Figure 5, an example of the Kaplan–Meier plot of a right censored data set generated from a Weibull distribution is displayed.

There are some other works that considered the problem of estimating reliability. Zhao *et al.* [35] studied storage reliability estimation. They initially considered nonparametric estimation for current reliability and then carried out parametric estimation based on the Weibull plot. Smooth estimation of the reliability function was achieved by Kulasekera *et al.* [38]. On the basis of many graphical results, they examined the performance of the Kaplan–Meier estimator smoothed with a suitable kernel estimator. Martínez *et al.* [39] proposed a

Figure 5. The Kaplan–Meier plot of data from Weibull.

support tool for maintenance management decision making using a nonparametric estimator for the reliability function. A number of graphs and diagrams were provided for visualization.

Reliability Growth Models

Many reliability data can be analyzed under the general framework of the nonhomogeneous Poisson process (NHPP) with a mean value function, $m(t)$, defined as the expected number of failures in $[0, t]$ [24]. The NHPP models are often utilized for analyzing reliability growth. Reliability growth analyses are quite useful to see the improvement in a product's reliability over time. It is also helpful in predicting future reliability of components or systems.

For analyzing reliability growth, the simplest and commonly used NHPP model is the Duane model [15]. Duane proposed a graphical approach that is based on plotting the

times between failures and the number of failures on a log-log scale. The plot tends to give a straight line if the assumed model is valid. One can also take the logarithm of the values and use normal scales. The plotted line also enables the estimation of parameters. Figure 6 shows the Duane plot of the data set by Currit *et al.* [40] based on a power-law model ($m(t) = at^b$); see Xie and Zhao [24]. The straight line provides a strong evidence that the power-law model is quite convenient, although some other models for this data set were also suggested by Xie and Zhao [24].

Xie and Zhao [24,25] proposed the use of the plotting the cumulative number of failures against the running time depending on the Duane model and other various models. They suggested using the plots for model verification and then for the estimation of parameters by giving illustrations for many real-life data sets. Wang [41] suggested a nonparametric graphical method to interpret

Figure 6. The Duane plot of data set by Currit *et al.* [40].

ill-collected data for repairable systems in vehicles. He presented the Mean Cumulative Repair Function plot, reliability growth plot based on power-law model, and reliability function plots based on the suggested method. Donovan and Murpy [42] proposed a new reliability growth model and developed the instantaneous mean time between failure (MTBF) equation for the new model. In another work by the same authors, some advantages of the new model over the Duane model were reported [43]. For more references about reliability growth models, see Codier [44].

Mean Cumulative Function (MCF) Plot

Some reliability data have repetition times of failures of repairable components. Since classical tools are not enough to describe, model, and analyze such data, methods that take into account the repetitive feature of the system are required. $M(t)$ (MCF) is the mean number (or cost) of recurrences up to time t , and the MCF plot is a useful and effective tool in expressing, modeling, and analyzing recurrence data. Nelson [16] suggested the use of nonparametric estimate of MCF in constructing its plot against time. It can be used for censored data and does not need any assumption. The plot is very simple to draw and can be used to estimate failure rates and other characteristics such as burn in time. See also Nelson [45,46] for a number of examples of the application of graphical analysis of repair data.

As for the reliability monitoring, control charting has been a popular graphical tool in the past decade. There have been quite a few works that studied the problem of monitoring failure data. Zhang *et al.* [47] considered exponential control charts to monitor the failure process of a reliability component or system. Batson *et al.* [48] utilized control charts based on normal, lognormal, exponential, and Weibull distributions to monitor field failure data. Xie *et al.* [49] implemented a control chart to monitor failure processes. Sürücü and Sazak [50] proposed a method to monitor the cumulative time elapsed between r failures using the three-parameter Weibull distribution. They also provided control charts and average run length curves to show the usefulness of the method in the reliability monitoring step.

Total Time on Test (TTT) Plot

TTT statistics were first introduced by Epstein and Sobel [21] who worked with exponential order statistics in life testing problems. Later on, the approach was applied in analyzing failure data for repairable and nonrepairable systems, aging analysis, maintenance planning, and dependent failure data analysis, starting with the works by Barlow *et al.* [51], Barlow and Campo [22], Barlow and Davis [52], and Barlow [53]. Bergman and Klefsjo [23] analyzed maintenance periods of repairable equipments by TTT plotting. Høyland and Rausand [54] utilized the TTT plot for data from nonrepairable systems. Kumar *et al.* [55] aimed

to estimate the operational reliability of machines in a Swedish mine and obtain the duration of optimal preventive maintenance by using TTT and double-TTT plots. Rao and Prasad [56] discussed the use of TTT plots for maintenance interval estimation for failure data having increasing failure rate. They also considered the TTT plots including covariate and showed its use with an example. Further theory and applications for the TTT plotting can be seen in a number of papers by Klefsjo and Westberg [57], Kumar and Westberg [58], Kvaloy and Lindqvist [59], Sun and Kececioglu [60], and Lai and Xie [61]. A generalization of the TTT plot was proposed by Kunitz and Pamme [62,63] who introduced aging plot for the identification of life distributions having bathtub shapes.

To explain the basic concept of TTT plotting, consider the following failure times of a certain component or a system: $0 \leq t_0 \leq t_1 \leq t_2 \leq \dots \leq t_n$, where t_i is the i th ordered failure time in a sample of size n . To see if there is a trend in failure structure, define the total time on the test at time t_i as

$$T_i = n \int_0^{t_i} R(t) dt, \quad i = 1, 2, \dots, n. \quad (5)$$

The scaled TTT plot is obtained by plotting S_i versus $F(t_i)$ where $S_i = \frac{T_i}{T_n}$.

The total time on the test at t_i is defined by

$$T_i = \sum_{j=1}^i (n - j + 1) (t_j - t_{j-1}), \quad i = 1, 2, \dots, n. \quad (6)$$

Then, the TTT plot is obtained by plotting S_i against the empirical cdf, $F_e(t_i) = i/n$. For other TTT plots based on different estimation methods of the survival function $R(t)$, readers can refer to Sun and Kececioglu [60] and Rao and Prasad [56].

OTHER GRAPHICAL METHODS

Many other studies have been published for analyzing reliability data through graphical methods. They are summarized below.

Balagurusamy and Misra [64] proposed a graphical method for the determination of the number of active redundant units and the computation of reliability parameters in an m -order system. Newby [65] utilized some graphical methods based on the aging properties of a number of failure distributions. Launer [66] presented graphical data analysis techniques based on the α -percentile residual life function [67,68] to study the empirical behavior of the hazard rate. Nicol *et al.* [69] described and discussed a graphical-model-based reliability estimation tool in their work. To study dependent failures, Walls [70] developed a graphical technique to estimate the reliability of repairable systems. Liu and Chiou [71] made use of Petri nets for failure analysis. Burrell [72] used a reliability plot technique to model citation data. The theory of limited expected value function was considered and extended by Quigley and Walls [73] for model identification of censored data. They utilized many graphical methods for their analysis. Trindade and Nathan [74] worked on field data and proposed some simple graphical methods for the reliability analysis of repairable systems. Halim and Tang [75] studied age heterogeneity for the MCF in repairable systems and presented some graphical representations. Different from other works, Donat *et al.* [76–78] studied probabilistic graphical models known as *graphical duration models* for analyzing reliability. Halim and Tang [79] suggested another graphical approach to obtain the confidence interval for the optimal preventive maintenance. Al-Garni *et al.* [80] used cumulative and MCF plots for field failures of aircraft systems. In a recent work by Saleh and Castet [81], many graphical methods were utilized to study the spacecraft reliability. For other related literature, the reader can refer to Hovis [82], Bergman and Klefsjo [83], Martin [84], Meeker and Escobar [85], Reineke *et al.* [86], and Nelson [87,88].

CONCLUDING REMARKS

Graphical methods are very useful tools in statistical analysis. They have widespread

use especially in the reliability area. Many analyses such as model verification and estimation of parameters for failure distributions are effectively conducted through these methods. In this article, we have presented the literature on graphical methods for reliability data, including the recent developments in the area.

Combinatorial optimization can be defined by a finite ground set $E = \{1, \dots, n\}$, a set of feasible solutions $F \subseteq 2^E$, and an objective function $f: 2^E \rightarrow \mathbb{R}$, all three defined for each specific problem. In this article, we consider the minimization version of the problem, where we seek an optimal solution $S^* \in F$ such that $f(S^*) \leq f(S)$, $\forall S \in F$. Combinatorial optimization finds applications in many settings, including routing, scheduling, inventory and production planning, and facility location.

While much progress has been made in finding provably optimal solutions to combinatorial optimization problems employing techniques such as branch and bound, cutting planes, and dynamic programming, as well as provably near-optimal solutions using approximation algorithms, many combinatorial optimization problems arising in practice benefit from heuristic methods that quickly produce good-quality solutions. Many modern heuristics for combinatorial optimization are based on guidelines provided by metaheuristics. Among these, we find genetic algorithms, simulated annealing, tabu search, variable neighborhood search, scatter search, path-relinking, iterated local search, ant colony optimization, swarm optimization, and greedy randomized adaptive search procedures (GRASPs).

In this article, we review the basic building blocks of GRASP, including solution construction schemes, local search methods, and

use of path-relinking as a memory mechanism in GRASP. The article is organized as follows. In the first section, we introduce a basic local search scheme. In the second section, we examine the relationship between the metaheuristic GRASP and local search. The third section covers construction schemes while in the fourth section, we introduce a memory mechanism in GRASP through path-relinking. Concluding remarks are made in the fifth section.

LOCAL SEARCH

Local search is a fundamental operator in GRASP heuristics. It is fully specified by a feasible starting solution $s_0 \in F$, an objective function $f(\cdot)$, for which we seek a local optimum, and a local neighborhood structure $N(\cdot)$ that restricts feasible moves in the search space. Local search in GRASP is applied from many distinct feasible starting solutions. Each application of local search in a GRASP heuristic results in a locally optimal solution, the best of which is output as the GRASP solution.

Consider the *neighborhood solution space* graph $\mathcal{X} = (S, M)$, where the node set S represents all feasible solutions of a combinatorial optimization problem and the edge set M corresponds to *moves* connecting neighboring solutions. A solution $s \in S$ is in the neighborhood $N(t)$ of a solution $t \in S$ if s can be obtained from t by making a small predefined change in t . If a solution $s \in N(t)$, then $t \in N(s)$, $(s, t) \in M$, and $(t, s) \in M$. Different neighborhood structures can be defined for a given combinatorial optimization problem.

The basic local search schemes take an initial solution, make it the current solution, and search the current solution's neighborhood for an improving solution. If one is found, it is made the current solution and local search is recursively applied to the current solution. The procedures terminate when no better solution exists in the current solution's neighborhood. Such local

search schemes require that the size of the neighborhood be such that its exploration can be done efficiently.

Algorithm 1. Basic local search algorithm.

```

 $t \leftarrow s_0$ ;
while there exists  $s \in N(t)$  such that  $f(s) < f(t)$  do
  |  $t \leftarrow s$ ;
end
return  $t$ ;

```

Algorithm 1 shows pseudocode for a basic local search algorithm. Local search starts at some node $s_0 \in S$ and makes it the current solution t , that is, $t = s_0$. At each iteration, it seeks a neighboring solution having a better objective function value than the current solution, that is, a solution $s \in N(t)$ such that $f(s) < f(t)$. If such a solution is found, it becomes the current solution, that is, $t = s$. These iterations are repeated until there is no better solution in the neighborhood $N(t)$ of the current solution t . In this case, solution t is called a *local optimum*.

Local search can be thought of as starting at a node $s \in S$ and examining adjacent nodes in graph $\mathcal{X}$ for an improving solution. In the *first-improving* variant, local search moves to the first-improving solution that it finds, whereas in the *best-improving* all neighboring solutions are evaluated and the local search moves to one of the best found. A compromise solution is used in *sampled local search* [1] where the neighborhood is sampled and the local search moves to the best of the sampled neighbors. One can think of this part of the search as *intensification*, since we concentrate on a small portion of the solution space.

Several approaches have been proposed to extend the basic local search scheme described above. These include methods such as variable neighborhood descent [2–7], variable neighborhood search [3, 8–12], short-term memory tabu search [13–24], simulated annealing [25–27], iterated local search [28–34], and very large-scale neighborhood search [35–37], which explore beyond the current solution’s neighborhood by allowing cost-increasing moves, by exploring multiple neighborhoods, or by exploring very large neighborhoods.

GREEDY RANDOMIZED ADAPTIVE SEARCH PROCEDURES

An effective search method needs to enable *diversification*. In carrying out local search, a good strategy should not focus the search on one particular region of the solution space, for example, around a solution built with a greedy algorithm. One alternative is to start local search from many randomly generated solutions with the expectation that there is a cost-improving path in $\mathcal{X}$ from one of those solutions to an optimal or near-optimal solution.

A GRASP repeatedly applies local search, starting from solutions that are constructed using a randomized greedy algorithm. The best local optimum found over all local searches is returned as the solution of the heuristic. Algorithm 2 shows pseudocode for a generic GRASP heuristic. At the completion of the randomized greedy phase the solution on hand is, for many problem instances, feasible. However, for some problem instances, it may be infeasible and requires that a repair procedure is applied to restore feasibility. Examples of GRASP implementations where repair procedures are needed to restore feasibility of the constructed solution can be found in Duarte *et al.* [38, 39], Nascimento *et al.* [40], and Mateus *et al.* [1].

An especially appealing characteristic of GRASP is the ease with which it can be implemented. Few parameters need to be set and tuned, and therefore, development can focus on implementing algorithms and data structures to assure efficiency. As we will see later, basic implementations of GRASP rely exclusively on two parameters. The first controls the number of construction/local search iterations that will be applied and the second controls the blend of randomness and greediness in the solution construction procedure. In spite of its simplicity and ease of implementation, GRASP is a very effective metaheuristic and produces the best-known solutions for many problems.

GRASP was first introduced by Feo and Resende [41]. See Feo and Resende [42], Pitsoulis and Resende [43], Resende and Ribeiro [44], and Resende [45] for surveys of GRASP

and Festa and Resende [46–48] for annotated bibliographies.

Algorithm 2. A basic GRASP in pseudocode.

```

 $x^* \leftarrow \infty;$ 
while stopping criterion not satisfied do
   $x \leftarrow \text{RandomizedGreedy}(\cdot);$ 
  if  $x$  is not feasible then
     $x \leftarrow \text{repair}(x);$ 
  end
   $x \leftarrow \text{LocalSearch}(x);$ 
  if  $f(x) < f(x^*)$  then
     $x^* \leftarrow x;$ 
  end
end
return  $x^*;$ 

```

GREEDY RANDOMIZED CONSTRUCTION

The greedy randomized construction methods of GRASP seek to produce a diverse set of good-quality starting solutions from which to start local search. This is achieved by adding randomization to the greedy algorithm. We illustrate here eight ways to do this. Solutions are built by adding one ground set element at a time to a partially constructed solution.

Semigreedy Construction

In the first construction scheme, called *semigreedy algorithm* by Hart and Shogan [49], at each step let the candidate set C denote all of the remaining ground set elements that can be added to the partial solution, and let $RCL(C)$ be a *restricted candidate list* made up of high-quality candidate elements. The quality of a candidate element is determined by its contribution, at that point, to the cost of the solution being constructed. A *greedy function* $g(c)$ measures this contribution for each candidate $c \in C$. Membership can be determined by rank or by quality relative to other candidates. Membership by rank, also called *cardinality based*, is achieved if the candidate is one of the q candidates with smallest greedy function value, where q is an input parameter that determines how greedy or random the construction will be. Membership by *quality* relative to other candidates determines a greedy

function cutoff value and only considers candidates with a greedy value no greater than the cutoff. To implement this, one usually makes use of a real-valued RCL parameter $\alpha \in [0, 1]$. Let $\bar{g} = \max\{g(c) \mid c \in C\}$ and $\bar{g} = \min\{g(c) \mid c \in C\}$. A candidate $c \in C$ is placed in the RCL only if $\bar{g} \leq g(c) \leq \bar{g} + \alpha \cdot (\bar{g} - \bar{g})$. Input parameter α determines how greedy or random the construction will be. Of these restricted candidates, one is selected at random and added to the partial solution. The construction is repeated until there are no further candidates. Algorithm 3 shows pseudocode for this construction procedure.

Algorithm 3. Greedy randomized construction: randomizing the greedy algorithm—semigreedy algorithm.

```

 $S \leftarrow \emptyset; C \leftarrow E;$ 
while  $|C| > 0$  do
  For all  $c \in C$  compute greedy function value  $g(c)$ ;
  Define  $RCL(C) \leftarrow \{c \in C \mid g(c) \text{ has a low value}\};$ 
  Select at random  $c^* \in RCL(C)$ ;
  Add  $c^*$  to partial solution:  $S \leftarrow S \cup \{c^*\};$ 
  Let  $C$  be the set of ground set elements that can
    be added to  $S$ ;
end
return  $S$ ;

```

Sample Greedy Construction

In the second construction scheme, called *sample greedy* by Resende and Werneck [50], instead of randomizing the greedy algorithm, a greedy algorithm is applied to each solution in a random sample of candidates. At each step a fixed-size subset of the candidates in C is sampled and the incremental contribution to the cost of the partial solution is computed for each sampled element. An element with the best incremental contribution is selected and added to the partial solution. This process is repeated until, as before, the construction terminates when no further candidate exists. Algorithm 4 shows pseudocode for this construction procedure. Sample greedy uses a parameter p to control the balance between greediness and randomness in the construction. Small values of p lead to more random solutions, while large values lead to more greedy solutions.

Algorithm 4. GRASP greedy randomized construction: sample greedy.

```

 $S \leftarrow \emptyset; C \leftarrow E;$ 
while  $|C| > 0$  do
    Randomly sample  $\min\{p, |C|\}$  elements from  $C$ 
    and put them in  $RCL(C)$ ;
    Select  $c^* = \operatorname{argmin}\{g(c) \mid c \in RCL(C)\}$ ;
    Add  $c^*$  to partial solution:  $S \leftarrow S \cup \{c^*\}$ ;
    Let  $C$  be the set of ground set elements that can
    be added to  $S$ ;
end
return  $S$ ;

```

Random Plus Greedy Construction

A possible shortcoming of the greedy randomized construction based on restricted candidate list is its complexity. At each step of the construction, each yet unselected candidate element has to be evaluated by the greedy function. In cases where the difference between the number of elements in the ground set and the number of elements that appear in a solution is large, this may not be very efficient. The third construction scheme, *random plus greedy*, was introduced in Resende and Werneck [50]. As is the case with the *sample greedy* construction scheme, the random plus greedy scheme also addresses this shortcoming.

In random plus greedy, a portion of the solution is constructed by randomly choosing p candidate elements and the remaining solution is completed in a greedy fashion. The resulting solution is randomized greedy. The value of p determines how greedy or random the construction will be. Small values of p lead to more greedy solutions where large values lead to ones that are more random.

Proportional Greedy Construction

The fourth construction scheme is the *proportional greedy* construction scheme. It was also introduced in Resende and Werneck [50]. In each iteration of proportional greedy, we compute the greedy function $g(c)$ for every candidate element $c \in C$ and then pick a candidate at random, but in a biased way: the probability of a given candidate $c' \in C$ being selected is inversely proportional to $g(c') - \min\{g(c) \mid c \in C\}$.

Reactive GRASP Construction

The fifth construction scheme is *reactive GRASP*. In randomized greedy construction procedures, the algorithm designer must decide how to balance greediness and randomness. A simple approach is to balance at random. For example, in the semigreedy construction with membership in the RCL by quality relative to the other candidates, the parameter α can be selected uniformly at random from the interval $[0, 1]$, so that each GRASP iteration uses a different α value and therefore has a different balance between greediness and randomness.

Prais and Ribeiro [51] showed that using a single fixed value for the value of RCL parameter α in the membership by quality relative to other candidates of the semigreedy algorithm often hinders finding a high-quality solution, which eventually could be found if another value was used. They proposed an extension of the basic GRASP procedure, which they call *reactive GRASP*, in which the parameter α is not fixed, but instead is selected at each iteration from a discrete set of possible values. The solution values found along the previous iterations serve as a guide for the selection process.

Prais and Ribeiro [51] define $\Psi = \{\alpha_1, \dots, \alpha_m\}$ to be the set of possible values for α . The probabilities associated with the choice of each value are all initially made equal to $p_i = 1/m$, $i = 1, \dots, m$. Furthermore, let z^* be the incumbent solution and let A_i be the average value of all solutions found using $\alpha = \alpha_i$, $i = 1, \dots, m$. The selection probabilities are periodically reevaluated by taking $p_i = q_i / \sum_{j=1}^m q_j$, with $q_i = z^* / A_i$ for $i = 1, \dots, m$. The value of q_i will be larger for values of $\alpha = \alpha_i$ leading to the best solutions on average. Larger values of q_i correspond to more suitable values for the parameter α . The probabilities associated with these more appropriate values will then increase when they are reevaluated. This reactive strategy is not limited to semigreedy procedures where membership in the RCL depends on relative quality. It can be extended to the other greedy randomized construction schemes, all of which need to balance greediness with randomization.

Long-Term Memory in Construction

The sixth construction scheme introduces long-term memory structures. Though reactive GRASP uses long-term memory (information gathered in previous iterations) to adjust the balance of greediness and randomness, Fleurent and Glover [52] observed that the basic GRASP does not and proposed a long-term memory scheme to address this issue in multistart heuristics. Long-term memory is one of the fundamentals on which tabu search [16,17] relies. Their scheme maintains a pool of elite solutions to be used in the construction phase. Later in this article, we discuss pools of elite solutions in detail. For now, all we need to know is that to become an elite solution, a solution must be either better than the best member of the pool, or better than its worst member and sufficiently different from the other solutions in the pool.

Fleurent and Glover [52] define a *strongly determined variable* to be one that cannot be changed without eroding the objective or changing, significantly, other variables and a *consistent variable* to be one that receives a particular value in a large portion of the elite solution set. Let $I(e)$ be a measure of the strongly determined and consistent features of solution element e from the ground set E . $I(e)$ becomes larger as e appears more often in the pool of elite solutions. It is used in the construction phase as follows. Recall that $g(e)$ is the greedy function value for candidate $e \in C$, that is, the incremental cost associated with the incorporation of element $e \in C$ into the solution under construction. Let $K(e) = F(g(e), I(e))$ be a function of the greedy and the intensification functions. For example, $K(e) = \lambda g(e) + I(e)$. The intensification scheme biases selection from the set C of candidate solutions to those elements $e \in C$ with a high value of $K(e)$ by setting their selection probability to be $p(e) = K(e) / \sum_{s \in \text{RCL}} K(s)$. The function $K(e)$ can vary with time by changing the value of λ , for example, initially λ may be set to a large value that is decreased when diversification is called for.

Biased Sampling Construction

The seventh construction scheme was introduced by Bresina [53] as *heuristic-biased stochastic sampling*. It is another way to depart from the uniform selection of candidate elements in the construction of a greedy randomized solution. Instead of choosing the next candidate element to add to the partial solution uniformly at random, heuristic-biased stochastic sampling suggests that any probability distribution can be used to bias the selection toward some particular candidates.

In the construction mechanism proposed by Bresina [53], a family of such probability distributions is introduced. They are based on the rank $r[\sigma]$ assigned to each candidate element σ , according to its greedy function value. The element with the smallest greedy function value has rank 1, the second smallest has rank 2, and so on. Several bias functions $b(\cdot)$ are introduced by Bresina, such as random bias where $b(r) = 1$, linear bias where $b(r) = 1/r$, log bias where $b(r) = \log^{-1}(r + 1)$, exponential bias where $b(r) = e^{-r}$, and polynomial bias of order n where $b(r) = r^{-n}$. Once all elements of the RCL have been ranked, the probability $\pi(\sigma)$ of selecting element $\sigma \in \text{RCL}$ can be computed as $\pi(\sigma) = b(r[\sigma]) / (\sum_{\sigma' \in \text{RCL}} b(r[\sigma']))$. In this scheme one can restrict candidates to be selected from the RCL or from the entire set of candidates, that is, make $\text{RCL} = C$.

Construction with Cost Perturbation

In the eighth construction scheme, called *construction with cost perturbation*, random perturbations are introduced in the original problem as a way of achieving randomness. The idea of introducing noise into the original costs to randomize a solution construction procedure is similar to that in the so-called *noising method* of Charon and Hudry [54,55].

Construction with cost perturbation can be more effective than the greedy randomized construction of the basic GRASP procedure in circumstances where the construction algorithms are insensitive to standard randomization strategies, such as selecting an element at random from a restricted candidate list. Ribeiro *et al.* [6] showed that

this is the case for the shortest-path heuristic of Takahashi and Matsuyama [56], which is used as one of the main building blocks of the construction phase of a hybrid GRASP they proposed for the Steiner problem in graphs.

Another situation where cost perturbations can be effective arises when no greedy algorithm is available for straightforward randomization as was the case of the hybrid GRASP developed by Canuto *et al.* [9] for the prize-collecting Steiner tree problem, which makes use of the primal–dual approximation algorithm of Goemans and Williamson [57] to build initial solutions using perturbed costs.

ADDING MEMORY TO GRASP THROUGH PATH-RELINKING

Path-relinking was originally proposed by Glover [58] as an intensification strategy exploring trajectories connecting elite solutions obtained by tabu search or scatter search [59–61]. Starting from one or more elite solutions, paths in the solution space graph leading toward other elite solutions are generated and explored in the search for better solutions. To generate paths, moves are selected to introduce attributes in the current solution that are present in

Algorithm 6. A basic GRASP with path-relinking heuristic.

```

P ← ∅;
f* ← ∞;
for i = 1, ..., imax do
    x ← GreedyRandomizedConstruction();
    if x is not feasible then
        x ← repair(x);
    end
    x ← LocalSearch(x);
    if i ≥ 2 then
        Randomly choose pool solutions  $\mathcal{Y} \subseteq P$  to relink with x;
        for y ∈  $\mathcal{Y}$  do
            xp ← PathRelinking(x, y);
            Update the elite set P with xp;
            if f(xp) < f* then
                f* ← f(xp);
                x* ← xp;
            end
        end
    end
end
P ← PostOptimize(P);
x* ← argmin{f(x), x ∈ P};
return x*;

```

the elite guiding solution. Path-relinking may be viewed as a strategy that seeks to incorporate attributes of high-quality solutions, by favoring these attributes in the selected moves.

The pseudocode in Algorithm 5 illustrates the mixed path-relinking procedure applied to a pair of solutions x_s and x_t . Mixed path-relinking [62] interchanges the roles of starting and guiding solutions after each move.

Algorithm 5. Mixed path-relinking procedure between solutions x_s and x_t .

```

Compute symmetric differences  $\Delta(x_s, x_t)$  and  $\Delta(x_t, x_s)$ ;
f* ← min{f(xs), f(xt)};
x* ← argmin{f(xs), f(xt)};
x ← xs; y ← xt;
while |Δ(x, y)| > 1 do
    m* ← argmin{f(x ⊕ m) : m ∈ Δ(x, y)};
    x ← x ⊕ m*;
    Update Δ(x, y) and Δ(y, x);
    if f(x) < f* then
        f* ← f(x);
        x* ← x;
    end
    t ← y; y ← x; x ← t;
end
x* ← LocalSearch(x*);
return x*;

```

The procedure starts by computing the symmetric differences $\Delta(x_s, x_t)$ and $\Delta(x_t, x_s)$ between the two solutions, that is, the set of moves needed to reach x_t from x_s and vice versa. Two paths of solutions are generated, one starting at x_s and the other at x_t . These paths grow out and meet to form a single path between x_t from x_s . Local search is applied to the best solution x^* in this path and the local minimum is returned by the algorithm. Initially, x and y are set to x_s and x_t , respectively. At each step, the procedure examines all moves $m \in \Delta(x, y)$ from the current solution x to solutions that contain an additional attribute of y and selects the one which results in the least-cost solution, that is, the one which minimizes $f(x \oplus m)$, where $x \oplus m$ is the solution resulting from applying move m to solution x . A best move m^* is made, producing solution $x \oplus m^*$. If necessary, the best solution x^* is updated. The sets of available moves are updated and the roles of x and y are interchanged. The procedure terminates when x and y are in each other's local neighborhood, that is, when $|\Delta(x, y)| = 1$.

Path-relinking is a major enhancement to the basic GRASP procedure, leading to significant improvements in solution time and quality. The use of path-relinking in GRASP was first proposed by Laguna and Martí [63]. It was followed by several extensions, improvements, and successful applications [6,9,44,50,64–68]. A survey of GRASP with path-relinking is presented in Resende and Ribeiro [69]. Two basic strategies are used. In one, path-relinking is applied to all pairs of elite solutions, either periodically during the GRASP iterations or after all GRASP iterations have been performed as a postoptimization step. In the other, path-relinking is applied as an intensification strategy to each local optimum obtained after the local search phase.

Applying path-relinking as an intensification strategy to each local optimum seems to be more effective than simply using it only as a postoptimization step. In general, combining intensification with postoptimization results in the best strategy. In the context of intensification, path-relinking is applied to pairs (x, y) of solutions, where x is a locally optimal solution produced by each GRASP

iteration after local search and y is one of a few elite solutions randomly chosen from a pool with a limited number `Max Elite` of elite solutions found along the search. Uniform random selection is a simple strategy to implement. Since the symmetric difference is a measure of the length of the path explored during relinking, a strategy biased toward pool elements y with large symmetric differences with respect to x is usually better than one using uniform random selection [50].

The pool is originally empty. Since we wish to maintain a pool of good but diverse solutions, each locally optimal solution obtained by local search is considered as a candidate to be inserted into the pool if it is sufficiently different from every other solution currently in the pool. If the pool already has `Max Elite` solutions and the candidate is better than the worst of them, then a simple strategy is to have the former replaces the latter. Another strategy, which tends to increase the diversity of the pool, is to replace the pool element most similar to the candidate among all pool elements with cost worse than the candidate's. If the pool is not full, the candidate is simply inserted.

Postoptimization is done on a series of pools. The initial pool P_0 is the pool P obtained at the end of the GRASP iterations. The value of the best solution of P_0 is assigned to f_0^* and the pool counter is initialized $k = 0$. At the k th iteration, all pairs of elements in pool P_k are combined using path-relinking. Each result of path-relinking is tested for membership in pool P_{k+1} following the same criteria used during the GRASP iterations. If a new best solution is produced, that is, $f_{k+1}^* < f_k^*$, then $k \leftarrow k + 1$ and a new iteration of postoptimization is done. Otherwise, postoptimization halts with $x^* \in \operatorname{argmin}\{f(x) \mid x \in P_{k+1}\}$ as the result.

The pseudocode in Algorithm 6 illustrates such a procedure. Each GRASP iteration now has three main steps. In the *construction phase* a greedy randomized construction procedure is used to build a feasible solution. In the *local search phase* the solution built in the first phase is progressively improved by a neighborhood search strategy, until a local minimum is found. In the *path-relinking phase* the path-relinking algorithm is applied

to the solution obtained by local search and to a randomly selected solution from the pool. The best solution found along this trajectory is also considered as a candidate for insertion in the pool and the incumbent is updated. At the end of the GRASP iterations, a *postoptimization phase* combines the elite solutions in the pool in the search for better solutions.

For some combinatorial optimization problems, a move m^* guided by the target solution is not guaranteed to result in a feasible solution $x \oplus m^*$ and the above-described scheme fails. Mateus *et al.* [1] proposed a new variant of GRASP with path-relinking suitable for such problems.

CONCLUDING REMARKS

This article considered basic building blocks needed to engineer heuristics based on the guiding principles of GRASP. These include randomized solution construction schemes, local search procedures, and the introduction of memory structures by way of path-relinking. One important topic that was left out of this article is that of parallel GRASP. The interested reader is directed to the survey of Resende and Ribeiro [70].

GROUP DYNAMICS PROCESSES FOR IMPROVED DECISION MAKING

LAWRENCE D. PHILLIPS
Department of Management,
London School of Economics
and Political Science,
London, UK

Many operations research (OR) practitioners work with groups. They do this for a variety of reasons: to ensure a full exchange of viewpoints on the issues being considered, to obtain data and information shared by several sources, to engage participants in constructive dialogue, to develop shared understanding of the issues, to create a sense of common purpose, and to gain commitment to the way forward. Models can help. They provide an output that integrates input data in a way that extends human capability.

But can they extend the capabilities of groups? Regan-Cirincione [1] showed that groups can outperform even their best member, given three conditions: (i) impartial facilitation of the group process, (ii) modeling of group judgments, and (iii) use of information technology to display the output of the computer model. These conditions enabled her groups to engage in discussions that challenged shared assumptions and developed new perspectives. This led to conclusions that lay outside the original range of individual participants' answers to the given task.

Encouraged by the improved communication and performance of facilitated work groups that use interactive modeling, facilitators of these groups recognized that some groups worked more effectively than others, and the differences did not seem to be attributable to the facilitation, the modeling, or the technology. It was apparent that group dynamics were at work, that covert processes were engaged beneath the surface, sometimes interfering with the task at hand. Knowledge of those processes could help the facilitator to help the group accomplish its task more effectively.

Because the literature on group dynamics is vast, it is necessary here to draw selectively from that literature, focusing only on findings that could make a difference to an OR practitioner engaged in problem solving with work groups. Four areas provide relevant findings: experiences with groups, experimental research with groups, studies of on-going groups, and systems for improved decision making.

EXPERIENCES WITH GROUPS

An experiential approach to the study of groups that began in the United Kingdom as group therapy for returning WWII military people showed that groups exhibited their own dynamic. This discovery initiated the study of group processes for ordinary working groups, that is, groups formed to achieve an objective. The studies, which have been ongoing since 1957 [2], are conducted in the "here-and-now," with participants taking part in observing and experiencing the work of the group, which is to learn about group dynamics. Participants are engaged in plenary sessions, large groups, small study groups, and intergroup exercises among the small groups, over a period of one to two weeks [3]. These temporary learning communities, first developed in the United Kingdom by the Tavistock Institute of Human Relations, and subsequently in the United States by the A. K. Rice Institute [4], as Working Conferences on Group Relations, are directed and staffed by qualified professionals drawn from the helping professions, at least some of whom are psychoanalysts or psychotherapists. They serve as consultants to the body of paying participants, who come on the conferences to learn about group dynamics and to explore how their learning might be utilized back in their home institutions.

The "Primary Task" and Group Competence

Achieving the group's objective is considered

to be the “primary task.” Without a clear understanding of the primary task, the group can become fragmented and unproductive. But even if the task is clear, the requisite competence must exist in the group to accomplish the task, and the group must be given adequate resources to carry out the activities needed to achieve their goal. For example, a large organization formed a new group whose lead manager asked his direct reports to devise a strategy for the group. The group’s discussion seemed to the facilitator to be unfocused, and a general air of dreariness pervaded the room, so the facilitator asked what was going on, and within a few minutes established that none of the participants knew what strategy was [5]. After a short tutorial on strategy by the facilitator, the group came alive and got on with the task.

The Group Life and Anxiety

Not surprisingly, the dynamics uncovered in these working conferences show that groups have many of the features of individuals. The group itself has a life, which is different from that of other groups, and often is quite distinctive. Just as individuals pursue goals, so the group pursues its goals. In doing so, the group life can shift and take on emotional tones that might facilitate or hinder achievement of the goals. A major source of anxiety experienced by participants comes into being when individual and group goals conflict, when what is best for the group is not experienced by one or more of its members as personally fulfilling. The resulting anxiety is dealt with in a mature group when individuals hold the anxiety and work it through, either by constructive debate within the group, by reconsidering their own goals, or just by waiting to see if a later resolution becomes possible.

“Basic Assumption” Behavior

Less mature groups might demonstrate one of five behavior patterns that can interfere with work on the primary task. Three of these were first identified by Wilfred Bion, who called them “basic assumption behavior” [2]: *fight/flight*, *dependency*, and *pairing*.

As anxiety builds, a flight from the primary task may be felt as the only way to preserve the security of the group, and one way to do this is to instigate a fight with the leadership or facilitator. A participant or group of participants might walk out or threaten to walk out if the present task continues unaltered, a *fight/flight* response to anxiety. Another way to respond to the anxiety is to depend on some real or imagined authority figure to act as the group’s savior. Often, it is the facilitator who is asked, “What do you think is best for us at this point?” Or, some outside authority is quoted, or a rule, or an institutional process. Whatever is chosen, this may be a sign that the group is abandoning responsibility for achieving the objective, thereby creating a *dependency* relationship. Group members act as if they have no skills, and depend on a leader or the facilitator to accomplish the primary task. The third pattern is *pairing*, an abandonment of the primary task in favor of developing the relationship between a pair of its members who are thought to be imbued with special capabilities to carry out the primary task. The group life is one of hope for the pair, who are expected to produce the goods—though to actually do so would destroy the hope, which is the objective the group wishes to maintain to deal with their anxiety.

Two more patterns identified since the publication of Bion’s book are *oneness* and *me-ness*. Pierre Turquet observed in some groups a culture of wanting to be at one with some higher power, to surrender themselves, and become one with a powerful force [6]. Achieving and maintaining this powerful sense of wholeness becomes the focus of group activity, replacing the feeling of anxiety in working on the primary task. This is, of course, seen in some religious groups, but it can also happen with no religious connotations in ordinary working groups when the good feelings of togetherness, or *oneness*, becomes the primary aim. The opposite of this behavior pattern, according to Gordon Lawrence [7], is a denial of the group’s social reality; the only reality is the core identity of each participant—*me-ness*. One or more participants resist becoming contributing members of the group. They maintain

an aloof stance, seldom contributing, never exposing their feelings. When many of the members take this stance, the group feels calm, unproductive, even dead. The facilitator feels increasingly that he or she must energize the group, but every attempt fails. This behavior pattern is more common in newly formed groups, particularly if members feel threatened by external social events, such as financial crises, threatened job losses, and volatility in the business or political environment.

The group relations conferences have built a substantial literature on group dynamics [8], which provides rich and in-depth perspectives on the functioning of groups, roles, authority, leadership, and organizations as systems. The experiential learning approach provides opportunities to develop skilled knowledge that cannot be obtained by direct teaching. The conferences broaden participants' repertoires of choices and enable them to be more effective as group members. Information about the UK's Tavistock/Leicester Conferences is available at <http://www.tavistock.org>, and about the US's Group Relations Conferences at <http://www.akriceinstitute.org>.

EXPERIMENTAL RESEARCH WITH GROUPS

Social psychology has a long tradition of research on group processes, extending back to the 1920s when Floyd Allport, a prominent American psychologist, argued that the proper task of sociology was to describe collective behavior, while the task of social psychology was to explain that behavior in terms of the individual. In other words, he believed that the psychology of groups was essentially the psychology of individuals. That pretty well killed experimental work on groups for a couple of decades, and it only revived during the 1950s, the subject becoming respectable once more as researchers became clearer about the individual/group distinction, and with the publication of proper experimental approaches that manipulated independent variables to see their effects on dependent variables [9,10].

It is now a vast literature. The fifth edition of Donelson Forsyth's comprehensive

textbook, *Group Dynamics* [11] includes about 3000 references. And it does not include any references to publications about group relations conferences, nor does "problem solving" appear in the index even though some of the research he reports is relevant to that topic. On the other hand, the whole of Maier's now out-of-print book [10] was devoted to applied research methods to determine how problem solving could be enhanced in groups. In between these extremes, whether or not indexed, the relevance of group dynamics to problem solving can be found in several recent books and journals [11–16]. Drawing from that literature, this section highlights seven of the many factors that influence group dynamics in problem-solving groups: group size, stage of development, norms, roles, status, cohesion, and leadership style.

Group Size

The size of the group greatly affects communication among participants. A very small group, of less than six participants, often works like a jazz group: frequent individual, brief solos, punctuated by the group working together. A small group, of 6–12 people, requires a degree of self-discipline on the part of each member in deciding whether or not to say something, which can lead to rising anxiety from unspoken disagreements. In mature groups, this can be a rich stimulus to problem solving, for the group is small enough for disagreements to be aired, but too large to allow unfettered displays of individual aggrandizement, thus creating the potential for constructive problem solving; the group works together like a chamber orchestra. Beyond about 12–15 people, the scope for individual contributions decreases, as in an orchestra, where a conductor is required to bring the orchestra to its full capability. For OR practitioners, groups composed of up to 12 people work best, though facilitators or leaders with strong facilitation skills [17,18] can effectively manage larger groups. Beyond about 25 people, problem solving becomes very difficult, though Schein claims that dialoging processes can be accomplished even in large groups [19].

Stage of Development

Newly formed groups often behave initially rather differently from established groups in which people are well acquainted. Facilitators of new groups often find that, after introductions and an initial polite exchange of views, the groups begin to become more aggressive. Sometimes, this arises as individuals jockey for leadership positions, like stags battling on the field for supremacy, and at other times to relieve pent-up frustrations about inadequate leadership, organizational dysfunction, or personal animosities. Eventually, members adapt to each other, develop agreed ways of behaving, and the group life becomes more stable; effective problem solving becomes possible. Described initially by Tuckman [20] and now described as “forming, storming, norming and performing” [21], research shows that this sequence can happen, but it by no means describes all newly formed groups.

Norms

Groups that continue to work together rather quickly develop ways of working, accepted practices, approved behaviors, and a culture that collectively define the “norms” against which all behavior is deemed either acceptable or unacceptable. In some cases, these norms are derived from individual and organizational core values, often embodying principles of fairness, equity, and respect. For example, the first Committee on Radioactive Waste Disposal, charged in 2004 with recommending a management strategy for the United Kingdom’s radioactive waste, began by developing a set of five key principles, the first of which was “To be open and transparent.” They then conducted themselves in a manner consistent with these principles, to the extent that a retrospective analysis of their successful work revealed an important implicit norm that had guided their work: “To respect alternative points of view” [22].

Norms usually contribute to accomplishing the group’s primary task, but norms can also have an inhibiting effect. As an example, a small group of three people believed they

had developed a new optical process for correcting dyslexia. As they discussed in a facilitated workshop how their system worked, it became less and less clear to the facilitator what the physiological basis for their system was. The group rejected all suggestions to validate their approach through plausible theory and proper scientific research—they constantly referred to successful cases, decrying the ability of research to “prove” their case. An anti-scientific norm had been established, and the facilitator was unable to help them.

It behooves outsiders brought in to help the group in its work to be sensitive to these norms, facilitating in concert with the norms where they support the group, but also challenging the norms when they seem to inhibit effective work.

Roles

At the beginning of a meeting with a group, a facilitator will be better able to understand the group dynamics in subsequent interchanges between members if he or she notes each person’s job role as they introduce themselves. Discussions of the issues relevant to the primary task are often role-related. In considering a new e-commerce enterprise, the managing director of a financial services company emphasized the opportunity presented by all three options being considered, the director of the organization’s bank favored the option that was most like a bank, the operations manager was most worried about the risk that all three of these untried ventures presented, and so forth. They spoke from their own experience, bringing to the discussion what they knew best. Some groups then engage in criticizing opposing points of view, hoping that will allow just one option to emerge as best. Instead, the facilitator encouraged everyone to speak freely, and used the diversity to populate a decision model that represented everyone’s concerns in the form of evaluation criteria. Role differences can be used to identify criteria against which the options are then appraised.

Roles can also be conferred on members by the group, usually explicitly as the work is partitioned and assigned to different participants, but sometimes unknowingly.

For example, a person who is an optimist and is known to have a good sense of humor can be cast in the role of the clown, expected to make light of difficult patches in the group's work. That defuses building frustration, and can help a group to deal with its mounting anxiety. A normally pessimistic individual may become the group's skeptic, always calling attention to the downside, alerting the group to the risks and uncertainties. Other roles, observed in group relations conferences, include that of savior, father, mother, victim, observer, spectator, commentator, expert, warrior, or leader. This person, implicitly "elected" by the group, becomes the spokesperson for feelings bubbling up in the group. The skeptic expresses everyone's skepticism, the savior provides a vision for the group, the expert provides the knowledge to accomplish the primary task, the observer maintains a quiet watchful eye on everything, and so forth. While each of those functions may help a group, an excessive implicit demand by the group may show that the group is unwilling to take on those responsibilities, and is relieved of anxiety as the nominated person takes over expressing what others are feeling. Usually, that person feels increasingly uncomfortable in the role thrust on him or her without quite knowing why. The facilitator can ask the group if that person is perhaps expressing feelings that the rest of the group are experiencing. This may defuse the growing burden and shift responsibilities back to the whole group.

Status

The status of individuals in the group can affect group productivity either favorably or unfavorably. Junior people are often reluctant to speak when high status individuals are included as members. That is particularly true in Eastern countries where saving face is important. It is necessary for the facilitator to address questions first to lower status participants because if a high status person speaks first, no lower status person will disagree. To a lesser degree, this also happens in the West.

However, if at the start of the group, the most senior person, usually the sponsor of the event, establishes the primary task and explains that anyone who holds information

that would be relevant to the task should feel free to speak, status differences will be less threatening. Information is established as a neutral commodity, to be shared by everyone. That enhances group productivity, unless people have been included in the group who do not have the capability to deal with the issues. This can happen if participants are drawn from more than two or three levels in the organization when strategy is being discussed, for their comments will often be seen as "down in the weeds" or paying too much attention to the trees with no view of the forest. The information they are sharing is at the wrong level of granularity.

Cohesion

The degree to which members of a group like each other can powerfully affect the group's performance; so common sense tells us. But research shows that groups can be effective even if people in it do not all like each other. Two forces are at work here. One is indeed interpersonal attraction, but the more important feature is commitment to the group's goals, norms and primary task [23]. The relationship between cohesiveness and group performance is reflexive: successful performance strengthens cohesiveness and cohesiveness enhances performance. Of course, if developing group cohesion replaces the primary task, even if everyone is committed to it, then performance toward achieving the goal will suffer. But if work on the primary task is maintained, and participants believe in the value of achieving their objectives, then positive interpersonal relationships help to strengthen the norms and the willingness of individuals to work hard in achieving the goals.

One threat to cohesiveness is worth noting: anonymity. Anonymous voting is sometimes cited as a good way to ensure that one person does not dominate a group, or to protect minority viewpoints. Most facilitators would agree that these two concerns can be handled with good facilitation skills, like asking everyone first to write down their view on something, then revealing them in turn, or simply asking participants who have not spoken for their views. One unidentified black ball in an anonymous vote can lower

trust among members as participants discuss who cast the dissenting vote. Research on this topic shows no consistent effect, so facilitators need to take care in using anonymous votes to ensure that the risk is justified by any possible benefits.

Leadership Style

Much of the research on leadership shows that different tasks require different leadership styles. What is appropriate in one context may not work in another. A group facing an immediate and serious crisis will benefit from a leader with a clear vision, the competence to take the group forward, and the energy to persist in spite of difficulties. Charisma is not necessary; it may help in some circumstances, but is not a necessary condition for group effectiveness [24].

In the setting of a work group in which the OR professional is acting as a facilitator, it is helpful to distinguish between process and content [25]. The processes adopted by a group in accomplishing its primary task can be guided by a facilitator, who then relieves the leader of attending to process. That leaves the leader of the group free to contribute to content. But here it is best for the leader first to listen to what others have to say and only later at an appropriate time to present his or her view, if that seems appropriate. A leader who is too directive can stifle the group. In general, group problem solving requires a consultative and participative style of leadership.

STUDIES OF ON-GOING GROUPS

Another approach to group dynamics is to study existing groups. Researchers in the three sets of studies reported here used various combinations of observation, interviewing, and examination of available records. All were concerned with decisions taken by individuals and teams in a variety of real-life settings. All used systematic methods to analyze their data and draw reasonable inferences and conclusions, but none engaged in laboratory-based research. For some, decision making was the focus, not group dynamics, but inevitably all commented on team functioning.

Small Work Groups

A team of researchers led by Richard Hackman [12] studied 27 teams at different levels in diverse organizations that covered top management groups, task forces, professional support teams, performing groups, human service teams, customer service teams, and production teams. Their observations of these teams at work showed the importance of structure: high performing teams are clear about their goals and objectives, are motivated to achieve their objectives and highly engaged in the primary task, are operating within well-defined roles, have been given the requisite authority and resources to fulfill the primary task, and are clear about the limits of their authority. All these findings are consistent with those of the group relations conferences.

Naturalistic Decision-Making Groups

Gary Klein [26] is a main contributor to the field of naturalistic decision making (see *The Naturalistic Decision Making Perspective*). He studied the decisions taken by highly proficient individuals in settings of “time pressure, high stakes, personal responsibility and shifting conditions.” The main contributions of his work to an understanding of group dynamics are twofold: (i) experience is crucial to accomplishing the primary task, and (ii) effective decision making under pressure is not analytical; there is always a time–accuracy trade-off (see *Decision Making Under Pressure and Constraints: Bounded Rationality*). He acknowledges that both non-analytical and analytical ways of problem solving are appropriate in many situations, which implies that effective teams are able to integrate intuition with thinking.

Political Decision Making

Janis and Mann [27,28] used the term *group-think* to describe a common feature of foreign policy decisions from 1940 to 1970 in the United States. They discovered “a deterioration of mental efficiency, reality testing, and moral judgment that results from in-group pressures.” They identified the conditions that stimulate group thinking: a cohesive

group which is under stress, dominated by a directive leader and insulated from information from outside the group, with participants focusing on one course of action rather than searching for alternatives whose merits can be appraised. They noted several features of the group dynamic:

- tightly knit group sharing an illusion of unanimity and correctness
- pressure exerted on dissenters to conform;
- unquestioned belief in the group's morality;
- scapegoating of "out-groups" as inferior;
- self-appointed "mindguards" shielding the group from contradictory information.

Leaders can protect against group-think by encouraging the airing of differences in viewpoints and listening to others before stating their own preferences. Also, inviting outside experts to join the group and establishing other groups to work on the same or different aspects of the problem legitimizes alternative viewpoints. For example, the European Medicines Agency (EMA) establishes two separate expert groups from different European Union countries to prepare reports on the benefits and risks of new medicinal products submitted to the EMA for approval. Each country mobilizes its own experts in preparing their reports, which are subsequently compared and discussed by the EMA's regulatory committee.

SYSTEMS FOR IMPROVING DECISION MAKING

Many of the above findings are integrated in group-based systems that can mobilize the capabilities of individuals to create high-performing teams. Two are mentioned briefly here: the Margerison and McCann Team Management System, and Decision Conferences. Each of these brings together many of the above research findings to create high-performing teams.

Team Management System

The research of Charles Margerison and Dick McCann identified nine types of work that characterize the activities carried out by effective teams. They found that people differ in their preferences for these types of work, so they developed a method for measuring people's work preferences [29] based on the psychoanalyst Carl Jung's theory of psychological types [30]. By focusing on work preferences rather than personality types, they developed a way of mapping people's work preferences onto the eight types of work. Their research shows that a balance of work preferences in a team helps to establish high levels of performance. They also developed an instrument for evaluating a person's skills in linking tasks and people. It is the combination of effective linking skills with group members contributing according to their work preferences that enables a group to function smoothly.

Decision Conferences

Since 1979 several thousand 2–3-day work groups, facilitated by impartial specialists in group processes and decision analysis, using on-the-spot modeling of information and participants' judgments, have enabled groups of key players to arrive quickly at an agreed way forward. Developments since 1982 at the London School of Economics brought together the technology of decision analysis (see *Foundations of Decision Theory*) with an understanding of group processes. The resulting intellectual technology, Decision Conferences [31], has demonstrated the advantages of this approach over ordinary working-group meetings [32]. *Decision Conferencing* uses a mixture of Decision Conferences, workshops, and other activities for sustained work with a client on large and difficult problems of strategy, evaluation, choice, prioritization, and resource allocation.

GUIDED LOCAL SEARCH

CHRISTOS VOUDOURIS
EDWARD P. K. TSANG

School of Computer Science and
Electronic Engineering,
University of Essex,
Colchester, UK

Many optimization problems found in the real world are computationally intractable (NP-Hard) due to the exponential increase in the number of possible solutions when increasing the problem size. Classical methods such as complete search often encounter great difficulty in solving such problems within reasonable computational times. This motivates the development of heuristic methods that sacrifice completeness. Some of the best known heuristics are local search (LS) methods. LS works by starting with an initial solution (randomly or heuristically generated), and then iteratively moving to “neighbor” solutions that improve the objective function. A “neighbor” solution is usually obtained by making a local (i.e., small) change to the current solution. LS terminates when it reaches a local minimum¹ (i.e., a state where the current solution is superior to all its neighbors), or computational resources run out. LS can obtain solutions of good quality very quickly. However, a major issue that negatively affects its efficiency is that it can be trapped in local minima, which halt the search, preventing the algorithm from reaching the global minimum. To overcome this problem, a class of techniques, which is referred to as, metaheuristics, has been introduced and grown in popularity over the years. Simulated annealing (SA) and tabu search (TS) are well known and representative techniques in this class.

¹We assume a minimization problem here but all the findings equally apply to a maximization problem.

Guided local search (GLS) [1] is another and relatively newer general metaheuristic algorithm. It is a higher level procedure that can sit on top of other heuristic methods to guide them to escape locally optimal solutions. GLS can be seen as a generalization of techniques such as GENET [2–4] and the min-conflicts heuristic repair method by Minton *et al.* [5] developed for constraint satisfaction problems. GLS also relates to ideas from the area of search theory as applied to naval search and rescue operations or deep-space surveillance on how to distribute the searching effort [6,7].

One key concept in GLS is to replace the objective function used by LS with an augmented objective function, which includes penalties associated to features of the candidate solutions. When LS is trapped in a local minimum, GLS dynamically modifies the augmented objective function by selectively increasing penalties for features present in the local minimum. This causes LS to escape by forcing it to move toward neighbor solutions that exclude these features. For the scheme to work, GLS requires the definition of solution features (i.e., attributes that can be used to discriminate between different solutions). It also requires a mechanism to select which features are penalized in a local minimum. The selection is normally done using a utility function, which for each feature present in a local minimum defines the utility of penalizing it. This utility function should be defined so that the search focuses where promise is shown while not neglecting the less-promising areas. From another viewpoint, the GLS penalization scheme should balance search intensification versus diversification.

Different metaheuristics apply different strategies to improve search and overcome the problem of local minima as shown in Table 1. SA and genetic algorithm (GA) employ a randomness component in a probability-based and population-based schema respectively to modify themovement

strategy. TS [8] exploits historical information in a memory-based approach to modify the set of neighbor solutions (i.e., neighborhood). GLS employs information in a penalty-based approach to dynamically modify the objective function.

GUIDED LOCAL SEARCH

GLS applies a penalty-based approach that can be superimposed on an LS algorithm with the aim of guiding it to escape local minima. The objective function is augmented with penalties which are increased when the LS settles in local minimum. Penalties are associated to solution features. A key component in GLS is thus the definition of the solution features. Solution features are defined to distinguish between solutions with different characteristics. GLS aims to penalize poor and costly characteristics that hopefully will be removed by the LS algorithm. Features are problem dependant and can be derived directly from the objective function which usually comprises one or more features. Examples of features are *whether the candidate tour travels immediately from city X to city Y* in the traveling salesman problem (TSP), and *whether the item I is assigned to item J* in the assignment problem. A simple indicator function can be used to determine

whether a solution exhibits a specific feature and therefore formally defines it.

GLS associates a cost and a penalty to each feature. Feature costs can often be defined by looking at the terms of the objective function and their coefficients. For instance, the costs of the example features mentioned above could be that of the traveling distance from city X to city Y in the TSP, and the carried cost of assigning item I to item J in the assignment problem. Feature penalties are initialized to 0 and they are incremented every time the LS settles in a local optimum and the feature is selected to be penalized.

Once features and their costs have been determined, GLS defines an augmented function h that will be used by LS (replacing the problem's objective function g):

$$h(s) = g(s) + \lambda \times \sum (p_i \times I_i(s)), \quad (1)$$

where s is a candidate solution, g an objective function that maps every candidate solution s to a numerical value, λ is a parameter to the GLS algorithm, i ranges over the features, p_i is the penalty for feature i (all p_i 's are initialized to 0), and I_i is an indicator function of whether s exhibits feature i :

$$I_i(s) = 1 \text{ if } s \text{ exhibits feature } i; 0 \text{ otherwise.} \quad (2)$$

Table 1. Overview of Strategies and Components of GLS and Other Well-Known Metaheuristics

Metaheuristic	The High-Level Strategy	Basic Component	Tuning Parameters
GLS	Using a penalty-based approach to dynamically modify the cost function	Features cost	λ
TS	Using a memory-based approach to dynamically change the neighborhood method	Solution attributes Short-term memory (STM) Long-term memory (LTM)	Tabu activation rules Tabu tenure [Aspiration criterion] [LTM measures and parameters]
SA	Using a probabilistic-based approach to allow nonimproving moves	Annealing schedule	Initial temperature Cooling rate
GA	Using a population-based approach that includes a mutation operator to involve (partially) random solutions	Genetic operators: reproduction, crossover, and mutation, Replacement strategy	Population size Crossover rate Mutation rate

Starting from an initial solution and using the augmented objective function h , an LS algorithm is applied until it reaches a local minimum. Provided with the local minimum solution, GLS selects which features to penalize to increase the value of h and force LS to move to a neighboring solution. The process is repeated until a termination criterion is met. The basic procedure of GLS is shown in Fig. 1. The basic idea of using the augmented objective function to force search out of local minima is illustrated in Fig. 2.

With regards to the feature selection mechanism, the intention is to gradually penalize “unfavorable” features when LS settles in a local minimum. The feature that has high cost affects the overall cost more and guiding the search toward solutions that avoid it when escaping out of the local minimum provides a strong intensification

mechanism, which favors high-quality solutions.

However, this intensification of search needs to be balanced with a diversification effect, which allows penalizing features of low cost when the high-cost features have been penalized several times. The current penalty value of a feature readily provides this information (i.e., the frequency of penalizing a feature). Combining the two factors above, the utility of penalizing feature i , given by $util_i$, under a local optimum s_* , is defined as follows:

$$util_i(s_*) = I_i(s_*) \times \frac{c_i}{1 + p_i}, \quad (3)$$

where c_i is the cost and p_i is the current penalty value of feature i . Note here that if a feature is not exhibited in the local optimum (as indicated by I_i), then the utility of

Figure 1. The basic procedure of guided local search.

Figure 2. The basic idea of GLS. An augmented objective function h is created and dynamically changed to force local search out of local minima of the original objective function g .

penalizing it is 0. The higher the cost of a feature (the greater c_i), the greater the utility of penalizing it. Besides, the more times that it has been penalized (the greater p_i), the lower the utility of penalizing it again. In a local optimum, the feature(s) with the greatest utility value will be penalized. When a feature is penalized, its penalty value is always increased by 1. The scaling of the penalty is adjusted by λ .

Considering the feature's cost and penalty as factors in selecting the feature to penalize helps GLS to focus its search effort on more promising areas of the search space: areas that contain candidate solutions that exhibit "good features," that is, features involving lower cost. On the other hand, penalties help to prevent the search from directing all effort to any particular region of the search space. Naturally the choice of the features, their costs, and the setting of λ may affect the efficiency of search. Experience shows that the features and their costs if derived directly from the objective function tend to work well with providing guidance to the LS. In many problems, the performance of GLS is also not too sensitive to the value of λ . This means one does not require too much effort to apply GLS to a new problem.

Measures to reduce the sensitivity of the λ parameter can also be adopted and they have been proven to improve algorithm performance in certain cases [9].

FAST LOCAL SEARCH

Another factor that affects the efficiency of LS algorithms is the size of the neighborhood that is checked at each iteration. LS algorithms, given a move operator, which introduces small changes to the current solutions, consider some or all the neighbors that can be derived from a candidate solution using that move operator. This usually results in a very large number of neighbors and, in cases such as greedy LS, we need to evaluate all solutions in the neighborhood of the current solution to decide the best one to move to. This is obviously time-consuming, and also affects metaheuristics such as GLS, which utilize LS in an iterative manner to examine numerous local minima. New algorithms that focus on redefining the neighborhood function have been proposed such as approximate 2-opt [10] for TSP.

Fast local search (FLS) was developed to restrict the neighborhood size, which leads to an improvement in the efficiency of LS especially in the context of the GLS metaheuristic. The aim of FLS is to focus LS on the promising neighbor solutions. The basic idea of FLS is to partition the neighborhood into a number of subneighborhoods. Each neighbor solution belongs to at least one subneighborhood.

To illustrate this partition, consider the single swap move operator used to obtain

the neighbors of a solution represented by a permutation of entities, for example, cities or jobs. In this case, the neighborhood of a solution is the set of all solutions obtained by swapping a variable's value with the value of another variable. A subneighborhood SN_i can be defined as the set of neighbors obtained by swapping variable i with other variables.

In FLS, each subneighborhood is associated with an activation bit. There are two states of any subneighborhood: active or inactive (i.e., the activation bit is either 1 or 0, respectively). Only active subneighborhoods are examined during the search. At the beginning of the search, all subneighborhoods are active. During the search, a subneighborhood becomes inactive when all candidate solutions it includes have been evaluated, but none of which provide a better move. However, if an improvement is found in a subneighborhood, then it remains active and the move is executed. This movement may include the process of activating some inactive subneighborhoods if they are expected to involve promising solutions. FLS stops when all subneighborhoods become inactive, that is, all activation bits equal 0, and there are no subneighborhoods to be examined.

The overall procedure could be many times faster than conventional LS. The bit setting scheme encourages chains of moves that improve specific parts of the overall solution. As the solution becomes locally better, the process is settling down, examining fewer moves, and saving enormous amounts of time which would otherwise be spent on examining predominantly bad moves.

A COMBINATION OF GLS AND FLS

Combining GLS with FLS is straightforward. The idea is to associate features to subneighborhoods. The associations to be made are such that for each feature we know which subneighborhoods contain moves that have an immediate effect upon the state of the feature (i.e., moves that remove the feature from the solution). After the penalties of features are increased, only the subneighborhoods corresponding to these features are activated.

The combined technique is called *guided fast local search* (GFLS).

GFLS is more sophisticated than the basic GLS algorithm using a number of FLS subneighborhoods corresponding to solution features, which are enabled/disabled during the search process. By reducing the size of the neighborhood, the computation time of an LS iteration is significantly reduced. Moreover, GFLS can provide better search focus after penalty increase by GLS by selectively activating only related subneighborhoods. This can dramatically shorten the time required by an improvement method to reoptimize the solution each time the augmented objective function is modified.

Overall, GFLS enables more LS iterations in a fixed amount of time and therefore offers more opportunities to GLS to guide the underlying LS process. It is much faster than basic GLS especially in large problem instances where repeatedly and exhaustively searching the whole neighborhood is computationally expensive. There is a chance some improving moves may be missed. The hope and premise is that the gain in "search speed" outweighs the loss in "search quality."

EXTENSIONS AND HYBRIDS

GLS has proved itself an efficient approach to tackle hard optimization problems. This has resulted in further research on GLS extensions and hybrids with other heuristics and metaheuristics. The outputs from this research, as will be discussed in this section, demonstrate the flexibility and generality of GLS.

Extensions to Guided Local Search

Use of tabu lists in GLS was found promising in the radio link frequency assignment problem (RLFAP) [11]. The motivation there was to avoid the possibility of misguiding the LS if too many penalties were built up during the search. Resembling the tabu lists idea, a limited number of penalties are used. When the list is full, old penalties are overwritten.

Aspiration criterion is another idea that comes from TS. Mills *et al.* [9] have described an extended guided local search

(EGLS), which utilizes the *improved-best* aspiration criterion modified specifically for penalty-based schemes. The basic idea is to use aspiration to favor promising moves. This can be done by simply examining the original objective function to check whether a new, better than previously found solution exists in the current neighborhood, before following the standard GLS scheme. In addition, the idea of random moves has been incorporated into EGLS to enhance GLS. LS is allowed to make a move at random according to some probability. The resulting algorithms improved the robustness of GLS over a range of parameter settings in the case of the quadratic assignment problem (QAP).

A distributed version of GLS was introduced by Basharu *et al.* [12] for solving distributed constraint satisfaction problems. The distributed guided local search (Dist-GLS) is following an agent-based paradigm introducing a messaging protocol communicating penalty decisions between problem solving agents working on different parts of the problem. It also incorporates additional heuristics to enhance GLS's efficiency in distributed scenarios.

GLS with a multiphase penalization procedure was proposed by Hifi *et al.* [13]. The modified procedure works either as a guidance for LS to escape local optima or as a restarting strategy. Tamura *et al.* [14] suggested a GLS procedure with a modified augmented objective function.

Guiding other Heuristics

Instead of simple LS, GLS can be generalized to guide other sophisticated heuristics in order to improve their efficiency. GLS has been hybridized with more complex LS methods such as variable neighborhood search (VNS) and large neighborhood search (LNS). The addition to VNS and LNS is the use of GLS to escape local minima encountered. Guided variable neighborhood search (GVNS), which is proposed by Kytöjoki *et al.* [15], combines GLS with VNS, which was successfully applied to the vehicle routing problem (VRP). The hybrid of GLS and LNS was proposed by Xiaohu and Haubrich [16]

in solving a network planning optimization problem.

GLS can sit on top of other metaheuristics such as GAs [17,18]. This has been demonstrated in guided genetic algorithm (GGA) [19–22]. GGA is a hybrid of GA and GLS. Besides the objective of extending the domain of both GA and GLS, a major objective of GGA is to further improve GLS by the means of population-based search. The basic idea is to employ GLS to bring GA out of plateau, a state when no progress has been made after n iterations (n is a parameter to GGA). GLS modifies the fitness function (which is the objective function) by means of penalties, using the criteria defined in Equation (3). GA will then use the modified fitness function in future generations. The penalties are also used to bias crossover and mutation in GA—genes that contribute more to the penalties are made more susceptible to changes by these two GA operators. This allows GGA to be more focused in its search. On the other hand, GGA can roughly be seen as a number of GLSs from different starting points running in parallel, exchanging material in a GA manner. The difference is that only one set of penalties is used in GGA, whereas parallel GLSs could have used one independent set of penalties per run. Besides, learning in GGA is more selective than parallel GLS: the updating of penalties is only based on the best chromosome found at the point of penalization.

GLS Hybrids

GLS has been hybridized with single point-based metaheuristics [e.g., TS [8]] and population-based metaheuristics (e.g., evolutionary computation), creating new frameworks that have been applied to a wide range of applications. Guided tabu search (GTS), as proposed by Tarantilis *et al.* [23,24], is a combination of GLS with TS. The basic idea is to control the exploration of TS by a guiding mechanism, based on GLS, which continuously modifies the objective function of the problem. Another hybrid of GLS and TS is proposed in the work of De Backer *et al.* [25].

GLS can sit on top of the basic LS in ant colony optimization (ACO). This has been

Table 2. GLS Extensions and Hybrids

Extensions/Hybrids	Description
Extended guided local search	Incorporates aspiration criterion (inspired from TS) and/or randomness components to the GLS.
Guided genetic algorithm	GLS operating on top of GA; it uses features and their penalties to bias GA operators.
Guided variable neighborhood search (GVNS), guided large neighborhood search (GLNS)	GLS combined with sophisticated local search algorithms: VNS and LNS.
Guided tabu search	Incorporates into a tabu search framework a guiding mechanism (inspired from GLS).
EDA/GLS	EDA is hybridized with GLS to help the latter from being trapped in a small local area.
Guided evolution strategy	ES is hybridized with GLS to help the latter from being trapped in a small local area.
Guided constraint search	A fast constraint search by using the GLS approach to ignore unfavored values in a variable's domain.
Dist-GLS	A distributed version of GLS.

demonstrated by the work of Hani *et al.* [26], which proposes ACO_GLS, a hybrid ACO approach coupled with a GLS, and applies the algorithm to an industrial layout problem, which is modeled as a QAP.

Zhang *et al.* [27] proposed a framework that incorporates GLS within an estimation of distribution algorithm (EDA) framework, in which each solution in the population of EDA performs a GLS. The resulting framework outperforms the stand-alone EDA and GLS in the QAP. The hybrid of GLS, FLS, and evolution strategy (ES) was introduced by Mester and Braysy [28]. An iterative two-stage procedure was proposed, where GLS plays a role in both phases to improve the LS in the first stage and to regulate the objective function and the neighborhood of the modified ES in the second one. Penalty variable neighborhood, which is incorporated in the algorithm, resembles the FLS principle, by which only a small set of the neighbors of the penalized feature are considered by the LS.

GLS's ideas of features, penalties, and utilities have been incorporated into new algorithms. Guided constraint search, which is proposed by Gomes *et al.* [29], borrows ideas from GLS to enhance the efficiency of pure constraint programming (CP) methods. The basic idea is to define a utility function, penalty parameter, and cost for each feature

(pair of variable/value). According to the utility function, at each iteration, only the best n most promising values of each variable's domain are examined, defining a subspace for the CP method. Those features which were considered but do not belong to a new best solution returned by the CP method are deemed bad features to be penalized.

A summary of the main extensions and hybrids of GLS as presented in this section is given in Table 2.

APPLICATIONS

GLS has been successfully applied to a wide range of problems. This section attempts to provide a comprehensive survey of these applications which are grouped here into five categories of applications: routing and scheduling problems, assignment problems, resource allocation problems, constraint optimization problems, and continuous optimization.

Routing and Scheduling Problems

Significant results for GLS and FLS have been obtained in their application to problems of this category, particularly the TSP and the VRP.

Given the positions of n cities, the task in TSP is to find the shortest closed tour

in which all cities are visited only once. The Lin–Kernighan (LK) algorithm is a specialized algorithm for TSP that has long been perceived as the champion of this problem [30] with some of its newer iterated implementations [31] still improving further the original method. GFLS using the 2-opt move operator was tested against LK [32] in a set of benchmark problems from the public TSP library TSBLib [33]. Given the same amount of time, GFLS found better results than LK in average. GFLS also outperformed other metaheuristics, namely, implementations of SA [34], TS [35], and GA [36] reported on the TSP. One must be cautious when interpreting such empirical results as they could be affected by many factors, including implementation details. But given that the TSP is an extensively studied problem, it takes something special for an algorithm to outperform sophisticated algorithms such as LK under any reasonable measure (“find me the best results within a given amount of time” must be a realistic requirement). It must be emphasized that LK is specialized for TSP but GLS and FLS are much simpler general purpose algorithms. Other applications of GLS combined with memetic algorithms [37] and with dynamic programming-based search technique [38], to the TSP were also reported. The application of GLS has also been extended to other variants of TSP. Padron and Balaguer [39] have applied GLS to the related rural postman problem (RPP), Vansteenwegen *et al.* [40] applied GLS to the related team orienteering problem (TOP), and Mester *et al.* [41] applied the guided ES hybrid metaheuristic to the genetic ordering problems [a unidimensional wandering salesperson problem (UWSP)]. In addition, the approach of applying GLS to TSP was deployed to solve other optimization problems, namely, network planning problems [16,42] and query reformulation [43]. Another application of GENET includes rail traffic control [44].

The VRP is another major application of GLS in this category. In a VRP, one is given a set of vehicles, each with its specific capacity and availability, and a set of customers to serve, each with specific weight and/or time

demand on the vehicles. The vehicles are grouped in one or more depots. Both the depots and the customers are geographically distributed. The task is to serve the customers using the vehicles, satisfying time and capacity constraints. This is a practical problem. Like many practical problems, it is NP-hard. Kilby *et al.* applied GLS to VRPs and achieved outstanding results [45,46]. As a result, their work was incorporated in Dispatcher, a commercial package developed by ILOG [25]. Recently, GLS and its hybrids have been applied to several variants of the VRP. GLS has been applied to the VRP with backhauls and time windows [47], and the capacitated arc routing problem [48]. GTS has been applied to VRP with time window [23,24], and also extended to other variants of VRP, including VRP with two-dimensional loading constraints [49], VRP with simultaneous pickup and delivery [50], and VRP with replenishment facility [24]. GLS hybrids with VNS [15] and with ES [28] have been applied to large-scale VRPs.

Processors configuration problem is a scheduling problem, in which one is given a set of processors, each of which with a fixed number of connections. In connecting the processors, one objective is to minimize the maximum distances between processors. Another possible objective is to minimize the average distance between pairs of processors [51]. In applying GGA to the processors configuration problem, representation was a key issue. To avoid generating illegal configurations, only mutation is used. GGA found configurations with shorter average communication distance than those found by other algorithms reported previously [20,21].

Assignment Problems

A generic problem under this category is the generalized assignment problem (GAP). In this problem, the task is to assign agents to jobs. There are two main constraints that should be satisfied: each job can be handled by only one agent, and each agent has a finite resource capacity that limits the number of jobs that it can be assigned. Assigning different agents to different jobs bears different utilities. Different agents will consume different amounts of resources when doing

the same job. In a set of benchmark problems, GGA found results as good as those produced by a state-of-the-art algorithm (which was also a GA algorithm) by Chu and Beasley [52], with improved robustness [22].

GLS hybrids have been proposed to the related QAP. Zhang *et al.* [27] proposed the GLS/EDA hybrid metaheuristic. In addition, the hybrid of GLS with ACO (ACO GLS) has been applied to a variation of the QAP [26].

Resource Allocation Problems

Problems in this category include the path assignment problem [53], maximum channel assignment problem [54], workforce scheduling problem (WSP) [55], and others.

The WSP [55] is a resource allocation problem, in which the task is to assign technicians from various bases to serve the jobs, which may include customer requests and repairs, at various locations. Customer requirements and working hours restrict the times that certain jobs can be served by certain technicians. The objective is to minimize a function that takes into account the traveling cost, overtime cost, and unserved jobs. In the WSP, GFLS holds the best-published results in the benchmark problem available to the authors [56].

The knapsack problem is another optimization problem, which can be considered as a resource allocation problem. Hifi *et al.* [13] applied a variation of GLS to the multiple choice multidimensional knapsack problem, a variation of the knapsack problem.

Constraint Satisfaction/Optimization Problems

Several combinatorial optimization problems concern the search of a feasible solution with respect to a set of constraints. In some cases, finding such a solution is impossible, and then the task becomes finding a solution that minimizes the number of unsatisfied constraints (relaxations).

More specifically, given a set of propositions in conjunctive normal form, the satisfiability (SAT) problem is to determine whether the propositions can all be satisfied while the maximum-satisfiability problem (MAX-SAT) asks for the maximum number of clauses which can be satisfied. The weighted

MAX-SAT problem is a variation of the MAX-SAT problem in which each clause is given a weight. The task is to minimize the total weight of the violated clauses (or maximize the total weight of satisfied clauses).

SAT, MAX-SAT, and weighted MAX-SAT problems have received significant attention over the years [57]. GLSSAT, an extension of GLS, was applied to both the SAT and weighted MAX-SAT problem [58]. On a set SAT problems from DIMACS, GLSSAT produced results comparable to those produced by WalkSAT [59], a variation of GSAT [60], which was specifically designed for the SAT problem.

On a popular set of benchmark weighted MAX-SAT problems, GLSSAT produced better or comparable solutions, more frequently than state-of-the-art algorithms, such as DLM [61], WalkSAT [59], and GRASP [62].

The RLFAP is another constraint optimization problem. In RLFAP, the task is to assign available frequencies to communication channels satisfying constraints that prevent interference [63]. In some RLFAPs, the goal is to minimize the number of frequencies used. Bouju *et al.* [63] is an early work that applied GENET, a method related to GLS, to radio length frequency assignment. For the CALMA set of benchmark problems, which has been widely used, GFLS reported the best results compared to all work published previously [64]. In the NATO Symposium on RLFAP in Denmark, 1998, GGA was demonstrated to improve the robustness of GLS [21]. In the same symposium, new and significantly improved results by GLS were reported [11]. At the time, GLS and GGA held some of the best known results in the CALMA set of benchmark problems.

GLS and FLS have been successfully applied to the related 3D bin packing problem and its variants [65–67], VLSI design problem [68], the natural language parsing problem [69], and graph set T-colorings problem [70]. A distributed version of GLS has been applied to graph coloring [12].

In another application, Lee and Tam [71] and Stuckey and Tam [72] embedded GENET in logic programming languages in order to enhance programming efficiency. In these

logic programming implementations, unification is replaced by constraint satisfaction [73]. This enhances efficiency and extends applicability of logic programming. Hoos and Tsang [74] provide an overview of LS in CP.

Continuous Optimization Problems

GLS has been applied to general function optimization problems [75]. Results show that GLS spreads its search effort across solution candidates depending on their quality (as measured by the objective function). Besides, GLS consistently found solutions in a difficult landscape with many local optima.

SUMMARY AND CONCLUSIONS

For many years, general heuristics for combinatorial optimization problems with most prominent examples, the methods of SA and GAs, heavily relied on randomness to generate good approximate solutions to difficult NP-hard problems. The introduction and acceptance of TS [8] by the operations research community initiated an important new era for heuristic methods, where deterministic algorithms exploiting historical information started appearing and being used in real-world applications. GLS described in this article follows this trend. While TS is a class of algorithms (where a lot of freedom is given to the management of the tabu list), GLS is more prescriptive (the procedures are more concretely defined). GLS heavily exploits information (not only the search history) to distribute the search effort in the various regions of the search space. Important structural properties of solutions are captured by solution features.

Solutions features are assigned costs and LS is biased to spend its efforts according to these costs. Penalties on features are utilized for that purpose. When LS settles in a local minimum, the penalties are increased for selected features present in the local minimum. By penalizing features appearing in local minima, GLS not only avoids the local minima visited (exploiting historical

information), but also diversifies choices for the various structural properties of solutions captured by the solution features. Features of high costs are penalized more times than features of low cost: the diversification process is directed and deterministic rather than undirected and random.

The GLS and GFLS methods are still in their early stages and future research is required to develop them further. The use of incentives implemented as negative penalties, which encourage the use of specific solution features, is one promising direction to be explored. Other interesting directions include fuzzy features with indicator functions returning real values in the $[0, 1]$ interval, automated tuning of the λ or α parameters, definition of effective termination criteria, alternative utility functions for selecting the features penalized and also studies about the convergence properties of GLS.

HAZARD RATE FUNCTION

SATYANSHU KUMAR UPADHYAY
Department of Statistics, DST Centre
for Interdisciplinary Mathematical
Sciences, Banaras Hindu
University, Varanasi, India

INTRODUCTION

The statistical analysis of lifetime data has become a topic of immense importance to researchers and practitioners engaged in many diverse areas such as engineering, medicine, biology, and social sciences. The lifetimes, sometimes also referred to as the *failure times*, *survival times*, and so on, are the results of life-testing experiments, where prototype of items or organisms are subjected to stresses and the environmental conditions that characterize the intended operating circumstances. These experiments may be laboratory-conducted experiments or may also be considered as natural processes giving rise to lifetimes. In addition, the lifetime should not always be treated as the complete duration of life from birth to death of an item or an individual rather it can simply be taken to mean an observation of a nonnegative random variable. A few typical examples may include the study of the incubation period of a disease such as the AIDS, the remission time of a specific type of cancer, employment duration of an individual in a particular company, the length of marriages of divorce cases in a country, and the time to failure of an item or equipment in engineering considerations, number of revolutions before the failure of, say, ball-bearings, and so on.

Given the results of a life test experiment, the accounts of the theory of statistics start from the premises that the observations correspond to random variables and there

exists a family of probability distributions for these random variables. The true distribution, giving rise to the process under consideration, is an unknown member of the family and the objective of the analysis is connected with some aspects of the unknown true distribution. Therefore, in a life-testing experiment, the first and the foremost task is to formulate a mathematical model or a probability distribution that adequately represents some features of the process. If we carefully see the mechanism of the process involved in the occurrence of an event, we find that there are many causes acting either in isolation or in a group, which may be held responsible for the happening of an event at a particular instant. It may not often be possible to isolate these causes for their separate mathematical accountability and, as a result, the choice of actual lifetime distribution becomes an art. The attempt to distinguish among various available models merely based on the actual observed data may lead to outright wrong conclusions since these distributions often exhibit absolutely different behavior at the tails and the observed data are sparse mainly on the right tail. Therefore, we need to appeal to a concept that is capable of differentiating among various possible distributions. Such a concept is known in the literature of lifetime data analysis as the *hazard rate*. The hazard rate is also referred by several other names in different disciplines. For example, it is named as the *force of mortality* in actuarial science to compute mortality tables [1] and as *intensity function* in the extreme value theory [2]. In statistics, its reciprocal for the normal distribution is known as *Mill's ratio* [3]. Tukey [4] obtains qualitative results concerning order statistics from distributions with monotonic hazard rates; such distributions are referred to as the *subexponential*. The hazard rate considered as a function of time is known as the *hazard rate function*.

Definition and Interpretation of the Hazard Rate

The notion of the hazard rate is particularly useful in lifetime distributions as it describes the way in which the instantaneous rate of failure for an individual changes with time. To clarify the ideas, we shall consider a few basic concepts and discuss separately the cases for continuous and discrete variables.

Case of Continuous Variate. Let T be a nonnegative random variable representing the lifetimes or the time until the occurrence of an event although the time units might be taken as “cycles,” “stress,” and so on, especially with reference to engineering statistics. Let $f(t)$ denote the density function and $F(t)$ denote the cumulative distribution function of T . Obviously, $F(t) = P(T \leq t)$ gives the probability that an event has occurred by the time t . Another quantity of interest may be the survival function, which is defined as

$$S(t) = 1 - F(t) = P(T \geq t) = \int_t^\infty f(x) dx, \quad (1)$$

which gives the probability of being alive at duration t , or more generally, the probability that the event of interest has not occurred by the time t . $S(t)$ is also called the *reliability function* at time t , when one is concerned with the lifetimes of manufactured items. It is to be noted that in general $S(t)$ is a monotone nonincreasing left continuous function with $S(0) = 1$, and $\lim_{t \rightarrow \infty} S(t) = 0$.

An alternative characterization of the distribution of T is given by the hazard function, or instantaneous rate of occurrence of the event. This can be defined as

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t | T \geq t)}{\Delta t}. \quad (2)$$

The numerator in Equation (2) represents the conditional probability of the occurrence of the event in the interval $(t, t + \Delta t)$ given that it has not occurred before time t , and the denominator is nothing but the width of the interval. Dividing the numerator and the denominator, the expression represents the rate of occurrence of the event per unit of time and taking the limit as the width of the

interval Δt goes to zero, we get the instantaneous rate of occurrence of the event at t given that it has not occurred to time t . In particular, $h(t)\Delta t$ is the approximate probability of occurrence of the event in the small interval of time t to $t + \Delta t$ given survival up to time t . If we put the usual definition of conditional probability for the numerator of Equation (2), the expression for $h(t)$ can be written as

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t)}{\Delta t P(T \geq t)}. \quad (3)$$

Note that the joint probability T is in the interval $(t, t + \Delta t)$ and $T \geq t$ is, of course, the probability that T lies in the interval $(t, t + \Delta t)$. Thus $h(t)$ can be equivalently written as

$$h(t) = \frac{f(t)}{S(t)}. \quad (4)$$

It is easy to see that the hazard function $h(t)$ provides an alternative formulation for representing the distribution of T . In fact, since $f(t) = -\frac{dS(t)}{dt}$, Equation (4) can be rewritten as

$$h(t) = -\frac{d}{dt} \log S(t),$$

which on integrating and using $S(0) = 1$, yields

$$S(t) = \exp\left(-\int_0^t h(y) dy\right). \quad (5)$$

That is, for any positive real t , the value of the survival function $S(t)$, of T at t , may be regarded as $\exp(-\text{area under } h(\cdot) \text{ to the left of } t)$ although the interpretation in terms of area may not always be justified. In any case, an obvious question arises that what happens at infinity. Since $S(\infty) = 0$, it implies that $S(\infty) = \exp(-\text{total area under } h(\cdot))$ must be zero. Therefore, all hazard functions must satisfy the following conditions:

$$\begin{aligned} \int_0^t h(u) du &< \infty, \\ \int_0^\infty h(u) du &= \infty, \end{aligned}$$

and $h(t) \geq 0$ for all $t \geq 0$. Thus, the hazard rate should not be regarded in any way as a probability density although it has a probabilistic interpretation.

The hazard function $h(t)$ can also be used to obtain the probability density function $f(t)$. Thus, from Equation (4) using Equation (5), we can easily write

$$f(t) = h(t) \exp\left(-\int_0^t h(y) dy\right). \quad (6)$$

The argument of the exponential term in Equation (6) is defined as the cumulative hazard function or the integrated hazard function and it can be considered as the sum of the risks that one faces in going from the time zero to t . Thus,

$$S(t) = \exp(-H(t)), \quad (7)$$

where

$$H(t) = \int_0^t h(y) dy. \quad (8)$$

Like the hazard function, the cumulative hazard function is not a probability. However, it is also a measure of risk: the greater the value of $H(t)$, the greater is the risk of failure by the time t .

Case of Discrete Variate. Sometimes the random variable T may be treated as a discrete variable, especially when the lifetimes are given in the form of a group data or when they represent integral number of cycles of some form. Suppose T can take on values $t_1, t_2, \dots$, and so on, with $0 \leq t_1 < t_2 < \dots$ and let $\varphi(t_i)$ denote the probability that T equals $t_i, i = 1, 2, \dots$. Obviously, $\varphi(\cdot)$ can be referred to as the *probability mass function* for the discrete random variable T . The survival function $S(t)$ can then be written as

$$S(t) = P(T \geq t) = \sum_{i: t_i \geq t} \varphi(t_i). \quad (9)$$

Note that $S(t)$, as for the continuous case, is a monotone decreasing but left continuous function with $S(0) = 1$ and $S(\infty) = 0$. The

hazard function at t_i can now be defined as

$$h(t_i) = P(T = t_i | T \geq t_i) \\ = \frac{\varphi(t_i)}{S(t_i)}, \quad i = 1, 2, \dots \quad (10)$$

Moreover, if we use the fact that $\varphi(t_i) = S(t_i) - S(t_{i+1})$, Equation (10) can be written as

$$h(t_i) = 1 - \frac{S(t_{i+1})}{S(t_i)}, \quad i = 1, 2, \dots \quad (11)$$

Thus, corresponding to Equations (5) and (6), $S(t)$ and $\varphi(t_i)$ can be written as

$$S(t) = \prod_{i: t_i < t} [1 - h(t_i)], \quad (12)$$

$$\varphi(t_i) = h(t_i) \prod_{j=1}^{i-1} (1 - h(t_j)), \quad (13)$$

which suggests that the probability, survival and hazard functions provide equivalent specifications of the distribution of a discrete random variable T as it was noted in continuous case.

An analog of $H(t)$ can be defined for discrete case as well but the cumulative hazard function is not an appropriate name for it [5]. It is so because $H(t)$ in this case, does not equal to the cumulative sum of $h(t_i)$ ($i: t_i < t$). One can therefore, simply consider $H(t) = -\log(S(t))$, where $S(t)$ is given in Equation (12).

Occasionally, situations arise when the distribution of T may have both discrete and continuous components. In such cases, the density function is sum of both discrete and continuous parts. The hazard function in such cases can be defined as above, whereas the survival function involves product of terms similar to Equations (5) and (12), which as usual is a monotone nonincreasing left continuous function on $[0, \infty)$ [5].

Further Discussion. The probability density (mass) function and the survival function (or, more generally, the cumulative distribution function $P(T \leq t)$) are the common representations of the distribution of a random variable T . The readers might not be

comfortable with the hazard rate, although it is a more specialized characterization of the distribution of a random variable especially when dealing with the lifetime data. As an immediate use of the hazard rate function one can say that greater hazard rate implies shorter life on an average. Let us consider, for instance, that lifetimes T_1, T_2 of two different objects have hazard rates $h_1(t)$ and $h_2(t)$, respectively. Further suppose that $h_1(t) > h_2(t)$ for all $t > 0$. Then,

$$\int_0^t h_1(y) dy > \int_0^t h_2(y) dy,$$

which implies from Equations (1) and (4) that

$$1 - F_1(t) < 1 - F_2(t)$$

and, therefore,

$$E(T_1) < E(T_2)$$

since $E(T_1) = \int_0^\infty [1 - F_1(y)] dy$.

Often, in many applications, the qualitative information may be available on how the hazard rate changes with the amount of time when an individual or item is subjected to testing. This information can be used to define $h(t)$, which can then be translated to define the functional forms of probability density (mass) or cumulative distribution (or survival) functions. For example, there may be models with nondecreasing (nonincreasing) hazard rate shapes or there may be models with hazard functions having some other well-defined characteristics.

An Example Based on Exponential Distribution. The simplest lifetime distribution may be obtained by assuming a constant hazard rate over time so that $h(t) = \lambda$ for all t . The corresponding survival function using Equation (5) may be written as

$$S(t) = \exp(-\lambda t). \quad (14)$$

This distribution is called the *exponential distribution* with parameter λ . The density may be obtained using Equation (4) as

$$f(t) = \lambda \exp(-\lambda t). \quad (15)$$

This distribution plays a central role in lifetime data analysis, although it is probably too simple to be useful in many applications [5,6].

The semiconductor devices can be considered to be important examples which do seem to exhibit constant hazard rate behavior and hence their lifetimes can be expressed by exponential distribution. It is to be noted that constant hazard behavior of devices does not necessarily mean that such devices never fail rather it should be interpreted that the devices having this characteristic do not appear to age. Thus, it can be said that a 20-year-old semiconductor device is just as likely to fail in the next moment as a brand new such device.

Some Typical Shapes of the Hazard Rate Function

Different hazard rate shapes can provide different kinds of distributions. Distributions with monotone hazard rates are of considerable importance and such distributions constitute a very large class. If $h(t)$ is increasing (decreasing) in $t \geq 0$ then $f(t)$ is said to be increasing hazard rate IHR (decreasing hazard rate DHR) distributions. For a mathematical convenience and added generality, concavity (convexity) properties have also been used for defining IHR (DHR) distributions whether or not a density exists [7]. Hence, we say that a distribution F has a DHR if its support is of the form $[a, \infty)$, and $h(t)$ is decreasing in $t \geq a$. For convenience, we may take $a = 0$. If the distribution F has a density, it can be verified by differentiating $\log [1 - F(t)]$ that $h(t)$ is increasing if and only if the support of F is an interval, and if on that interval, $\log [1 - F(t)]$ is concave. Similarly, F is DHR if and only if the support of F is $[0, \infty)$ and $\log [1 - F(t)]$ is convex in $t \geq 0$ [3].

A well-known example can be the Weibull distribution with density

$$f(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{(\beta-1)} \exp \left[- \left(\frac{t}{\theta} \right)^\beta \right]; \theta, \beta, x > 0, \quad (16)$$

where θ defines the scale parameter and β determines the shape of the distribution. The

hazard rate of this distribution can be written as

$$h(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{(\beta-1)}. \quad (17)$$

Obviously, the Weibull density has IHR for $\beta > 1$, DHR for $\beta < 1$, and it coincides with the well-known exponential distribution for $\beta = 1$. It is to be noted that the form of the exponential distribution given in Equation (15) is a reparameterized form of the model that can be obtained from Equation (16) taking $\lambda = \theta^{-1}$ and $\beta = 1$.

Figure 1 provides the increasing, decreasing, and constant shapes of the hazard rate function with the corresponding densities shown in Fig. 2. These figures are drawn using Weibull distribution when the scale parameter θ is set to unity. A similar pattern can be observed when considering gamma distribution [6] with density

$$\frac{1}{\Gamma \kappa} \left(\frac{t}{\theta} \right)^{\kappa-1} \exp \left[- \left(\frac{t}{\theta} \right) \right]; \quad \theta, \kappa, t > 0.$$

That is, the gamma model is IHR for $\kappa > 1$, DHR for $\kappa < 1$, and it has a constant hazard rate for $\kappa = 1$. In the discrete case, a well-known example is provided by the negative binomial distribution with probability mass

Figure 1. Hazard rate for the Weibull distribution showing increasing ($\beta > 1$), decreasing ($\beta < 1$) and constant trends ($\beta = 1$).

Figure 2. Probability density function of the Weibull distribution for different values of shape parameter.

function given by

$$\binom{-\alpha}{j} p^\alpha (p-1)^j; \quad \alpha > 0, 0 < p < 1, \\ \text{and } j = 0, 1, \dots$$

This model is also IHR for $\alpha > 1$ and DHR for $\alpha < 1$ and coincides with the geometric distribution for $\alpha = 1$. The case $\alpha = 1$ is characterized by the constant hazard rate [3].

A typical hazard rate may generally exhibit a so-called bathtub or “U”-shaped appearance. Such a hazard rate shape is shown in Fig. 3. If, for example, individuals

Figure 3. A typical bathtub-shaped hazard rate function.

in a population are followed right from their actual birth to death, such shapes are usually found appropriate. Bathtub or “U”-shaped hazard rate clearly indicates three distinct regions with two change points. The first, called the *initial failure region* or a region due to birth defect, is characterized as a DHR. In engineering context, this region represents early failures due to material or manufacturing defects. Good quality control and burn-in product testing usually eliminate many substandard devices, and thus avoid this high initial failure rate region. Similarly, we may follow the pattern in human population, where we often have early deaths resulting from birth defects or various other causes leading to high infant mortality. The second region (Fig. 3), called the *chance* or *random failure region*, is characterized by a near constant hazard rate. It represents chance failures caused by sudden stresses, unusually severe and unpredictable operating conditions, and so on. To eliminate these, one would require a device that is over designed for the vast majority of situations. The situation of a near constant hazard rate can be noticed in human population as well where it is usually observed that the death rate drops after attaining an initial age of, say, 5 years and then becomes relatively constant until the age of, say, 30 years or so. The third and the final segment in the bathtub shape is called the *wear-out failure region* and it is typified by an increasing failure rate (Fig. 3). In engineering context, such a situation is usually observed because of the equipment deterioration, accumulated shocks, fatigue, and so on. In human population, this deteriorating pattern in the form of IHR occurs primarily because of aging.

Modeling for the data sets that exhibit bathtub shapes has always been a tough task. There have been several proposals given in the literature to model such behavior [8–10]. One such proposal is to combine at most three different distributions, often the Weibull or some similar model, separately for decreasing, constant, and increasing shapes of the hazard rate. Sometimes combination of two different models may also result in the required bathtub shape. Generalization

or modification of Weibull density can be another important approach to obtain the bathtub shape of the hazard rate function. A number of models have been proposed in the literature using this approach. The key idea is simple. Consider the functional form of the hazard rate of Weibull distribution and modify this form so that it is capable of representing the bathtub shape as well. This modification can be done by either adding a new parameter in the hazard rate of the Weibull model or by manipulating the mathematical form of the hazard rate function so that it does provide bathtub shape as well. Exponentiated Weibull, Weibull extension, and modified Weibull models are a few important families obtained by generalizing or modifying the two-parameter Weibull family [11].

Model Detection Using Empirical Hazard Function

Given a model, one can always find the hazard rate function with the help of Equation (4), (10), or (11) using the fact that the concerned variate is continuous or discrete. A question, however, arises that can we get an approximate shape of the hazard rate function from the data in order to facilitate the tentative selection of a model. The answer to the question is “yes,” we can. This can be accomplished by obtaining the nonparametric estimate of the hazard rate function from the given set of observations and then drawing the estimated hazard function so obtained with respect to time [12]. This curve will help us to tentatively guess for a model for the data in hand. For example, if the curve so drawn is increasing, one can try to rely on the models such as Weibull and gamma, with shape parameter greater than unity. A word of remark: this is only a tentative guessing; one should always consider one of the various available tools for testing the goodness of fit of the observed data with the considered model. In addition, if more than one model is appearing proper for the data in hand based on the nonparametric estimated hazard plot, one can even try to compare the various proposed models in order to obtain the most appropriate candidate [13].

HAZARDOUS MATERIALS TRANSPORTATION

VEDAT VERTER
Desautels Faculty of Management,
McGill University, Montreal,
Quebec, Canada

Hazardous materials (hazmats), such as gases, flammables, explosives, and radioactive materials are an integral part of our industrial lifestyle. In most cases, the point of production and consumption for these materials are different, and hence they need to be transported in significant volumes. For example, oil extracted from oil fields is sent to refineries, which ship their products (such as heating oil and gasoline) to storage tanks at different locations within a country. As another example, polychlorinated biphenyls (PCBs) are collected at many industrial installations, such as old power generation and transfer stations, and shipped to special waste management facilities for incineration. Accidental release of hazmats during transportation can be harmful to people, property, and the environment. Despite deregulation of transportation industry around the globe, governments at federal, provincial, and municipal levels remain involved in assessing and mitigating the public and environmental risks of dangerous goods shipments. Note that there are many stakeholders including the shippers, the carriers, the nongovernmental organizations, the public at large as well as the governmental agencies. To complicate hazmat logistics even further, different government levels often have different jurisdiction. For example in Canada, the railroads are under federal authority, the highways and hazmat storage sites are under provincial jurisdiction, whereas the city roads are governed by municipalities. A wide range of hazmat types with different impact zones are shipped between many origin–destination pairs in each jurisdiction. The economic viability of the transport sector is also a crucial

factor for regulators in designing policies to mitigate the public and environmental risks of dangerous goods.

In its 2005–2006 biennial report on hazardous materials transportation, the US Department of Transportation (US DOT) estimated that every day there are over 800,000 hazmat shipments in the United States, which amounts to about 9 million tons. The US Chemical Manufacturers Association forecast that the total volume of hazmat transportation will surpass 5 billion tons by 2020. The most recent Trucking Commodity Origin and Destination (TCOD) Survey by Statistics Canada, however, estimated that 106 million tons of dangerous goods were shipped by trucks in 2004, which amounts to 17.4% of all freight shipments across the Canadian roads (Provencher, 2008). Note that the survey focuses on for-hire trucks only, excluding the shipments carried by the companies' own trucks (e.g., Petro-Canada) and by foreign companies. In addition, 36 million tons of dangerous goods were moved by Canadian National (CN) and Canadian Pacific (CP) in 2004, and this represents 12.5% of all rail freight. The US DOT estimated that around 140 million tons of hazmats were carried via rail across the country in 2007. Overall, a significant majority of hazmat shipments are by road and rail, whereas marine shipments in bulk and in containers represent the third major mode of transportation.

There are about 40 major hazmat accidents in Canada and about 75 serious incidents in the US annually. In August 2008, for example, an explosion at Sunrise Propane's distribution facility in Toronto affected 580 homes and caused 1.5 million dollars in cleanup costs. There were also two fatalities and a number of nearby residents injured by the blast and flying debris. Note that this was only one of the 150 large propane distribution centers in Ontario. Within a few days of this accident, a CSX train derailment in Tennessee became a hazmat incident because one of the 17

derailed railcars—all carrying automotive products—hit a chemical storage facility owned by White House Utility district. Although such accidents are often not catastrophic, increasing shipment volumes raise the possibility of a gruesome event, such as the 1979 train derailment in Ontario that resulted in a chlorine leak and consequently required the evacuation of 200,000 people. A more recent example is the November 2005 collision in Sinaloa, Mexico that involved an ammonia truck and caused 39 fatalities.

The people living and/or working around the roads heavily used for dangerous goods shipments incur most of the transport risk. The policies that are available to government agencies for mitigating hazmat transport risk can be categorized into two main groups with respect to their underlying philosophy: proactive and reactive. The latter group of policies aims at confining the undesirable consequences of a hazmat incident after the occurrence of the accident. The development of emergency response plans—that involves the establishment of a network of responder teams specializing on different hazmat types—is the most popular example of reactive policies. The consequence of an accident can be reduced by better coordination of responder teams and faster response times to the incident site. In contrast, the proactive risk mitigation policies aim at reducing the likelihood and consequences of hazmat incidents *a priori*. The restrictions on the use of certain road segments by trucks carrying dangerous goods, the establishment of inspection centers for such trucks, and the improvements in the durability of railcar containers used for hazmat transportation are common examples in this category.

TRANSPORT MODES FOR HAZMAT

The majority of the literature on hazmat transportation focuses on road shipments. The development of reliable techniques for transport risk assessment [1–3] and the optimization of the routing decisions for potentially hazardous shipments [4,5] are the two main goals of these papers. Typically, a carrier's perspective is adopted by focusing

on transportation of a single type of hazmat between a single origin–destination (O–D) pair. Although train shipments can reach comparable levels to truck shipments from a total tonnage perspective, particularly in Europe and Canada, the literature on rail transport of hazmats is sparse. There are a number of differences between rail and highway routing of hazmat transportation. Rail infrastructure is typically owned and maintained by private rail companies. Consequently, railroad networks are sparse and do not contain as many potential alternative routes as highway networks. More importantly, railroads do not have tracks circumventing major population centers that are comparable to interstate beltways around metropolitan areas. A given shipment is likely to be handled by more than one railroad carrier, whereas truck shipments are usually limited to a single company. The rail carriers are motivated to maximize their portion of the movement. In a recent paper, Verma and Verter [6] highlighted additional differences between the two transport modes. A train usually carries nonhazardous and hazardous cargo together, whereas these two types of cargo are almost never mixed in a truck shipment. Furthermore, a rail tank car has roughly three times the capacity of a truck-tanker (80 tons and 25–30 tons, respectively), and the number of hazmat railcars varies significantly among different trains. Another important characteristic of trains is the possibility of incidents that involve multiple railcars.

The recent studies mostly focus on improving tank car safety through better container design, in an effort to reduce the likelihood of a release in the event of a derailment. By studying the risks associated with non-pressurized materials, Raj and Pritchard [7] report that the DOT-105 tank car design constitutes a safer option than DOT-111. Barkan *et al.* [8] show that tank cars equipped with surge pressure reduction devices experienced lower release rates than those without this technology. Barkan *et al.* [9] conclude that the speed of derailment and the number of derailed cars are highly correlated with hazmat release accidents. Recently, Barkan *et al.*

[10] study the trade-off between increased damage resistance and greater exposure to accidents, while minimizing the probability of release. They point out that the optimal container thickness varies with tank car configuration.

The comparison of rail and road from the viewpoint of hazmat transport risk attracted the attention of some researchers. In particular, Glickman [11] observed that the accident rate for significant spills (when release quantities exceed 5 gallons or 40 pounds) is higher for truck tankers than for rail tank cars, and that rail tank cars are more prone to small spills. Saccomanno *et al.* [12] showed that the safer mode varies with the hazmat being shipped, and differing volumes complicate comparison between the two transport modes. Leeming and Saccomanno [13] reported that although hazmat railway shipments pose more risk to residents in the vicinity of railroad tracks, the total risk of these two transport modes does not differ significantly. Their conclusion is based on a single case study in England. There is no consensus among researchers with regards to the best transport mode in terms of public and environmental safety. The transport mode choice varies with the type of hazmat to be carried.

Intermodal transportation is increasingly becoming popular since it enables the carriers to take advantage of the synergy between the scale economies in rail and the flexibility of road shipments. The US DOT estimates that multimodal transportation of dangerous goods will increase drastically in the near future. The transfer of freight from one mode to another takes place at intermodal terminals that require significant capital outlays at the construction phase. Consequently, the intermodal transport network design literature has focused on cost minimization, and we are aware of only two exceptions: Rondinelli and Berry [14] make a brief reference to the possible environmental impact of such facilities, and Taniguchi *et al.* [15] incorporate the resulting traffic congestion when deciding the location of similar facilities in Japan.

TRANSPORT RISK ASSESSMENT

The main concern associated with hazardous materials shipments is the undesirable consequences of an incident that involves the release of the cargo from its container. Typically, such incidents are caused by the involvement of the vehicle in an accident, such as a truck collision or a train derailment. The resulting leakage, fire, and/or explosion may cause fatalities, major and minor injuries as well as environmental damage. In an effort to minimize such undesirable consequences, the emergency response guidelines mandate the initial evacuation of a certain area around the incident site. The size of the evacuation area varies with the type of hazmat involved in the accident. Some hazmats are not only extremely dangerous, but they can travel long distances upon being airborne. Chlorine, for example, can travel up to 10 km depending on the wind conditions. The residents who live near the roads and rail tracks that are often used for moving hazmats are exposed to the risk of suffering the undesirable consequences of an incident. The public's resistance to the use of nearby routes for hazmat transportation usually depends on their perception of the associated risks rather than the expert assessments.

Various definitions of transport risk have been proposed in the earlier literature: a popular measure is the number of people living within a threshold distance from the routes used by hazmat trucks. This model is originally suggested by Batta and Chiu [16] and it emphasizes population exposure to hazmats rather than the occurrence of an incident. Revelle *et al.* [17] used a weighted combination of population exposure and transportation cost in finding routes for radioactively contaminated fuel rods. Alternatively, incident probability is suggested as a risk measure by Saccomanno and Chan [18] and Abkowitz *et al.* [19]. This model focuses on the likelihood of having a hazmat incident during transportation and ignores the possible undesirable consequences. Consequently, it is more suitable for the hazmats with relatively small danger zones. The expected risk model, which is also endorsed by the US

Figure 1. Alternative routes between Chicago and Atlanta. [Source: Adapted from Erkut and Verter [21].]

DOT provides a means to incorporate both the probability and the consequence of a hazmat incident [20]. The single commodity, single origin–destination problems studied in these papers are typically faced by hazmat carriers and they can be reduced to a shortest path model using the risk measure as arc impedance.

Through a detailed analysis of the United States road network, Erkut and Verter [21] demonstrated that the optimal routes for potentially hazardous trucks vary considerably with the risk representation in a mathematical model, and hence the choice of risk measure may have important repercussions. For example, Fig. 1 depicts the path that minimizes the expected risk of a hazmat shipment from Chicago to Atlanta as well as the shortest path for this (O–D) pair. Note that these two paths are geographically very different. Erkut and Verter [21] also showed that the best path for a transport risk

measure could perform poorly under some of the other risk measures.

Verter and Kara [22] incorporated risk assessment techniques in a GIS framework and presented a critical evaluation of the hazmat transportation activity in Quebec and Ontario. To date, this paper remains as the largest-scale risk assessment study in the scholarly literature. There are more than 100,000 gasoline truck shipments in these two Provinces annually. Figure 2 depicts the possible outcome of routing all these shipments according to four different criteria. The thickness of each road segment is proportional to the number of gasoline trucks using that link. Note that the routes that minimize the total distance and the total incident probability are similar, because the highest quality roads with the least likelihood of an accident are those that connect the urban centers. The apparent similarity between the minimum population exposure and the minimum expected risk routes is due to the fact

Figure 2. Alternative routing of gasoline shipments in Ontario and Quebec. [Source: Adapted from Verter and Kara [22].]

that both of these risks are driven by the spatial distribution of the population.

Verter and Kara [22] highlighted the significance of the topology of the road network by showing that a risk mitigation measure that would be effective in Toronto (i.e., the use of minimum population exposure routes) would not be as effective in Montreal, since the hub-shaped road network does not allow the trucks to bypass the heavily populated island.

For more information on health and environmental risk assessment.

THE REGULATORS' PERSPECTIVE

There are only a few exceptions to the carrier-oriented perspective of the prevailing literature. List and Mirchandani [23] presented the first multicommodity formulation for routing hazmats and locating hazardous

waste treatment facilities. The application of their model in Albany, New York, is based on a number of simplifications, including the representation of each population center as a point and the shipment of a single type of hazmat. Iakovou *et al.* [24] provide a multicommodity network flow model for the problem of routing hazardous vessels. Their model is applied to the transportation of crude oil and refined petroleum products in the Gulf of Mexico. The aim was to avoid overloading certain links of the transport network, which usually happens when the optimal route for each shipment is identified independent of the other shipments.

Kara and Verter [25] presented the first mathematical formulation for the problem of identifying the road segments that need to be closed for hazmat trucks. In the context of the road network of Western Ontario, they compare alternative policies for regulating the use of road segments. Recognizing the extent

of the cost-risk trade-off between the governments' and carriers' ideal solutions, Verter and Kara [26] developed a formulation that can generate compromise solutions for the hazmat road network design problem. Marcotte *et al.* [27] demonstrated that the use of tolls for hazmat trucks is a more efficient policy for mitigating transport risk than prohibiting the use of certain road segments. Following up on Kara and Verter [25], Erkut and Alp [28] propose an alternative formulation as a Steiner tree selection problem and proposed a greedy heuristic. This topology takes away the carriers' freedom in route selection and reduces the bi-level problem to a single level. Erkut and Gzara [29] consider a bi-objective cost and risk minimization version of the network design problem, and present a heuristic algorithm that exploits the network flow structure at both levels.

Focusing on other policy tools available to policy makers, Berman *et al.* [30] develop a model to determine the best locations for specialized hazmat emergency teams, whereas Verter and Erkut [31] highlight insurance requirements as an effective means for influencing major hazmat carriers' route choices. The former study shows that it is possible to drastically improve the responsiveness of specialized emergency response teams in the Quebec–Windsor corridor by relocating their stations. The latter study, however, points out that the insurance requirements can be effective in incentivizing the use of routes with less transport risk only for the carriers with large fleets. Gendreau *et al.* [32] develop heuristics for determining the location of inspection stations to be established on a network so as to ensure compliance with the regulator's requirements pertaining to route choices, maximum load and speed, driver's fatigue level, insurance requirements, container specifications, and so on.

AVENUES FOR FUTURE RESEARCH

In closing this introductory article on hazardous materials transportation, the reader is referred to Erkut *et al.* [33] for a comprehensive review of the recent research on the topic. For an overview of the earlier

literature, the reader is referred to Erkut and Verter [34] and List *et al.* [35]. This section highlights two fruitful avenues for future research: (i) transportation of hazmats in urban centers, and (ii) the use of intermodal transportation for dangerous goods shipments.

The prevailing research on truck shipments of dangerous goods is focused on highway transportation rather than the shipments through congested city streets. A significant majority of the trucks carrying potentially dangerous cargo, however, enters urban areas to make their delivery, for example, to gas stations. There is a need for the development of analytical approaches that incorporate the differentiating characteristics of urban transportation. In particular, the traffic congestion on the streets and the dynamic patterns of population distribution within urban centers need to be incorporated in transport risk assessment and truck routing models. The development of new risk assessment methods for shipments through urban streets is needed. In this domain, the potential harm to the other people on the road is as significant as the risk imposed on the people living within a threshold distance from the road. Note that the latter has been the sole focus of the prevailing risk assessment methods for highway and shipments. From the perspective of the regulator, risk mitigation policies need to be adapted to the urban environment. For example, the arrival of specialized emergency response teams to the incident site might be delayed due to heavy traffic congestion on the city roads. Also, the implementation of toll pricing policies for the use of certain city road segments by dangerous goods trucks may become a necessity [27].

The other potentially significant area for future research is the use of intermodal transportation networks for hazmat shipments. As a means of competing with the trucking industry, major railway companies are increasingly investing in intermodal transportation (see *Decision Problems and Applications of Operations Research at Marine Container Terminals*). This gives them the ability to benefit from the flexibility of short haul truck shipments (i.e., inbound

and outbound drayage), while enjoying the scale economies in long haul rail shipments. Note that the transfer of the cargo from trucks to railcars is done at intermodal terminals, and many of these yards are being built near (or within) urban centers. The alternative strategies regarding the construction of multimodal transport yards, which are becoming increasingly common for dangerous goods shipment, need to be studied. Given their significant impact on the spatial distribution of transport risk, these fixed facilities need to be a significant element of the risk assessment and policy development frameworks. Early work on intermodal transportation of hazmats identified the major risk and cost trade-offs between the drayage and rail operations [36]. Although intermodal transportation constitutes a major opportunity for improving hazmat logistics, the arising problems are often quite complex from a methodological perspective.

HELLENIC OPERATIONAL RESEARCH SOCIETY

NIKOLAOS MATSATSINIS
Department of Production Engineering and
Management, Technical University of
Crete, Crete, Greece

HISTORICAL ASPECTS

The Hellenic Operational Research Society (HELORS—www.eeee.org.gr) was founded in 1963 by pioneering Greek scientists, with the objective of promoting the study and applications of operational research (OR) methodology, for the benefit of the Hellenic economy and society. HELORS' corporate headquarters is located in Athens, where the administrative council sits in privately-owned offices.

HELORS is a member of the "Association of European Operational Research Societies—EURO" within the "International Federation of Operational Research Societies," (IFORS).

The society promotes and disseminates OR/scientific management by every possible means, as a tool for making rational and documented decisions. In the 46 years since its inception, HELORS has evolved into a scientific entity with an important presence in the scientific and economic life of the country, with hundreds of members who are outstanding for their theoretical backgrounds, entrepreneurial endeavors, and professionalism.

HELORS initially went through a period (1963–1980) where most of its efforts lay in the dissemination and advancement of the methods and techniques of OR to organizations and staff of the private and public sectors. To meet these objectives, seminars, lectures, and conferences were organized under the auspices of HELORS that extended the use of OR in making rational

decisions in topics such as strategy, political organization, and managerial control.

Current results of a company's activities, *inter alia*, are the employment of operational researchers in businesses and organizations, national defense general staff, and elsewhere. The emergence of the value and importance of OR from HELORS led to the introduction of relative courses in universities. As a consequence, numerous students became acquainted with the principles and the philosophy of OR, and in turn, commonly apply them in their employment environments. Enterprise and organization managers, by experiencing the constructive results of operational research work, recognized OR as a valuable tool of decision making and problem solving.

Subsequently, a second creative and fruitful period follows (1980–today), in parallel with socioeconomic, technological, and political changes in Europe and other parts of the world. These changes influence significantly the Hellenic economy, which should in turn, become more productive and competitive [1–5].

In 1984, the Macedonia–Thrace annex was founded, aiming primarily at the growth of OR in the greater area of Balkans and at an improved organization and communication of the members of northern Greece. This annex enumerates more than 120 members and is located in Thessaloniki. Among other activities, the Macedonia–Thrace annex organizes four different Balkan conferences, various seminars in industrial management and regularly participates in educational programs of neighboring Balkan countries when funded by the European Union.

GOALS

Adaptable to current trends, HELORS' main objective is to participate and contribute substantially to business and organization development of the private and as the public sectors, by upgrading their human

resources. This can only be achieved with appropriate education and training. Thus, HELORS organizes educational seminars, lectures of broad social thinking and business, as well as conferences dedicated to functional demands of businesses, and so on, and hence contributing to the establishment of crucial relationships between expert researchers of the field of management and the wider social community.

This new reality extends HELORS field of action which approaches better the enterprise and organization; presents and analyses a broad spectrum of recent management, marketing, decision making, financial, and new technology practices. HELORS' prestige and successful choices of people ensures the quality and success of its events. With all these activities, HELORS has gained an outstanding position in the field of scientific management. Today, HELORS is recognized for

- educating business managers;
- organizing conferences and workshops in topics related to crucial issues in management science;
- presenting economic and social reality.

The conditions under which HELORS will operate in the next few years are expected to create

- a Greece that is more "European," with the upgrading of institutions, management, the way of thinking and acting;
- enterprises and organizations that are more rationally organized, that will have to a greater extent assimilated modern management and information technologies;
- a very competitive market for management staff where greater importance will be given to the timely update of information and new technologies and the opportunities for exchange of ideas and experiences, especially at an international level.

These predicted conditions define HELORS' strategic choices as these are

shaped by the Executive Council and the members' General Council and are summarized by the following triptych:

- extroversion, participation in common issues, development of initiatives for the researching of problems, cooperation with other associated bodies, further strengthening of international contacts;
- close cooperation with dynamic enterprises in a mutual relationship, support for managerial staff development programs and the implementation of new technologies and ensuring material and moral support since the objective is for enterprises to determine that HELORS is "their issue";
- ensure that the members of HELORS receive all the benefits that provide for professional achievement and social recognition.

By all indications, the aspirations of earlier generations of management scientists for the emergence of a new way of thinking (i.e., systematic approach to the problems of businesses and justified business decision making) are gradually fulfilled in our country.

The large family of operational researchers should continue to play a catalytic role, which has faithfully served over the years, to account for the human potential of the field of science management and to enhance business practices by adopting modern technologies and methods.

HELORS will continue its effort for the consolidation of all management scientists who have the knowledge and the willingness to develop initiatives for further development and exploitation of these resources. The service package for their members will include:

- information on international and local activities;
- information on technological advances in their field through seminars, workshops, lectures, and so on;
- exchange of experiences on the subject of their work through workshops, work groups, and seminars;

- member participation in continuous training, either as lecturers, or as participants;
- provision of specialized software from the HELORS offices, special library, and so on.

With these services to its members, HELORS will try to help in the promotion of the modern, systematic way of thinking in addressing problems, professional competence in complex roles, and social sensitivity in order to upgrade our economy.

MEMBERS

Today the number of members of HELORS stands at 750. This human potential is the most important element of the assets and comprises its invaluable capital. The number of members, ranks HELORS as the fifth largest among the countries of IFORS (41 countries, in which HELORS has been a member since 1966).

Members are mainly engineers, economists, mathematicians, and so on. Over 60% of the members hold a Master's degree in operational research/business administration, and 15% hold a doctoral degree.

The important input that operational researchers have provided is recognized and demonstrated by the fact that many members of this organization are now senior executives in private companies and organizations, and several other members have repeatedly held top management positions in public organizations.

Also many members of the company have become professors in higher education institutions and by their educational and research work, they contribute efficiently to the establishment of OR as a management problem-solving tool. Members have published theoretical and applied articles on OR, in prestigious Greek and foreign scientific journals. The new members easily find employment in the private or public sector.

ACTIVITIES

The following are indicative activities of the HELORS.

Presidents of HELORS

The following are the Presidents of HELORS:

1963–1974:	General Radamathis Spanogiannakis, Founder of HELORS
1974–1976:	Professor Dimitris Ksirokostas, National Technical University
1976–1978:	Professor Ioannis Pappas, National Technical University
1979–1980:	Professor Dimitris Xirokostas, National Technical University
1981–1984:	Professor Dimitris Blesios, University of Piraeus
1985–1988:	Professor Dimitris Papoulias, Kapodistrian University of Athens
1989–1990:	Professor Konstantinos Papis, University of Piraeus
1991–1994:	Konstantinos Vasiliadis, Executive Manager
1995–1996:	Spiros Pashentis, Executive Manager
1997–1998:	Professor Konstantinos Papis, University of Piraeus
1999–2004:	Professor Ioannis Siskos, University of Piraeus
2005–2008:	Professor Dionisios Giannakopoulos, Technical Institute of Piraeus
2009...	Professor Nikolaos Matsatsinis, Technical University of Crete

Golden Medals

HELORS has decided to establish the award “Gold Medal of Operational Research” for distinguished Greek scientists, who have made important advances in operations research. “Gold Medals of Operational Research” have been awarded to the following:

1999	General Radamathis Spanogiannakis, Hellas
2000	Professor Dimitris Bertsekas, Massachusetts Institute of Technology (MIT), United States
2001	Professor Panagiotis Pardalos, University of Florida, United States
2002	Professor Spiros Makridakis, INSEAD, France
2003	Professor Dimitris Ksirokokostas, National Technical University, Hellas
2004	Professor Dimitris Bertsimas, MIT, United States
2005	Professor Ioannis Siskos, University of Pireaus, Greece
2006	Professor Biron Papathanasiou, Aristotle University of Thessaloniki, Greece
2007	Professor Evangelos Pashos, University Paris-Dauphine, France
2008	Professor Aristidis Sissouras, University of Patras, Greece
2009	Professor Konstantinos Zopounidis, Technical University of Crete, Greece

Work Groups

For better organization and efficiency, the HELORS operates in working groups. Currently, the following working groups have been approved and operate specialized in different topics:

- Multicriteria Decision Analysis (Group coordinator: Yannis Siskos), and

- OR in health (Group coordinator: Prof. Aris Sissouras).

The Multicriteria Decision Analysis group has already organized seven meetings in multicriteria analysis and one seminar on multiple criteria decision aid.

In the near future, more working groups are expected to be approved and become operational.

Publications

Scientific Journal. HELORS issues the scientific journal “Operational Research: An International Journal–ORIJ.” ORIJ publishes high quality scientific papers that contribute significantly to the fields of OR/MS. ORIJ covers all aspects of OR including optimization methods, decision theory, stochastic models, simulation, game theory, queueing systems, inventory and reliability, among others. Articles published in ORIJ present new theoretical insights and developments, as well as real-world case studies illustrating the practical implementation of OR. Contents include papers exploring the interactions of OR/MS with other relevant disciplines such as information technology, computer science, artificial intelligence, soft computing, and electronic services. This is a unique feature of ORIJ as compared to other existing OR journals and provides a means to explore new directions in OR/MS research in an interdisciplinary context. ORIJ also publishes overview papers from eminent scientists in significant fields of OR/MS; these review the state-of-the-art in these fields. As of 2008, ORIJ is published by Springer (<http://www.springerlink.com/content/1109-2858>).

Conference Proceedings. HELORS issues proceedings of the conference that it organizes.

Newsletter. Every 3 months the HELORS prepares an electronic press releases (newsletter) which includes:

- activities of HELORS,
- HELORS conferences,

- OR—an international journal,
- upcoming surveys,
- call for papers in European and international conferences,
- call for papers in special issues magazine in EU,
- fellowships on EU issues outside Greece,
- links to interesting sites,
- EU journals.

Conferences

Twenty-one national conferences have been organized since 1977, covering the current problems of the Hellenic economy and society. The choice of topics, exchange ideas, and intense questioning during the conference contributed significantly to the promotion of OR in our country and to the promotion of the Hellenic operational researcher in Hellenic businesses. HELORS has also organized six special conferences in more specialized topics.

More than 4500 people have participated in HELORS conferences. More than 1000 announcements have been made during these conferences and can be divided into applied research works and those that promote basic scientific research. Business executives, professors, and executives of public sector have made announcements in topics related to strategy, organization, management and control, technology, and so on.

The participants have benefited in multiple ways from the conferences, by listening to the opinions and attitudes of other members and thus, gaining important experience. HELORS also organized six international conferences. One of the top conferences was the 12th International Conference on OR of IFORS which was held in Athens, Greece, 25–29 June 1990, and was recognized as the best in terms of quality and content of IFORS conferences. It brought together about 700 scientists from around the world. The company has also organized the European Conference EURO XX OR and the Management of Electronic Services in Rhodes from 4–7 July 2004.

Special mention should be made of the organization under the initiative and

responsibility of Macedonia–Thrace annex: four Balkan conferences in OR (1988, 1993, 1995, and 2002) have been held in Thessaloniki with the participation of researchers from the Balkan countries (Albania, Bulgaria, Serbia, Former Yugoslav Republic of Macedonia, Romania, Turkey, and so on).

Training and Seminars

So far, more than 100 lectures have been given by prestigious members of the HELORS, on current issues of OR and the methodology for making rational decisions.

From its inception until today, HELORS has held more than 700 seminars, gaining thus exceptional, extensive, and valuable experience. This is one of the most remarkable and important efforts of HELORS in education and vocational training. The training topics, since early years, fully cover all methods and techniques of operations research and many areas, directives, and questions developed in the management science.

The seminars offered by HELORS are divided into seven groups:

- marketing,
- finance,
- computers and new technologies,
- media-planning resources,
- quality management,
- management of materials-distribution,
- decision systems administration.

Approximately 13,500 executives from the private and public sectors have participated in the company's seminars. Participants, through an evaluation procedure, recognized the practical value and usefulness of the topics covered by the seminars. The majority of the trainees' implemented techniques and methods of OR in their employment companies with positive results.

The workshops of the organization are characterized by topics of current interest and high quality services. The instructors are professors of theoretical training and practical experience, with great knowledge and experience of the field.

Each seminar is structured with appropriate balance between theory and practice. This also comprises the main difference between HELORS and other similar companies. HELORS tries to teach the participants a new way of thinking, analyzing, and solving business problems, so that they instead of randomly applying methods and tools in their businesses, they will be able to choose the most appropriate methodology.

Projects

The most recent indicative studies undertaken by the HELORS are given below:

1. completion of part of the project "SPEKS—Creating value through change: anthropocentric approach bringing together social partners, enterprises, and knowledge providers" (contracting body: Labor Institute of GSEE);
2. research implementation on the Hellenic police officer satisfaction (contracting body: Institute of Police Studies, Training and Documentation);
3. implementation of two studies within the research project entitled WFP CRETE "continuing adaptation of human resources to new conditions through an integrated approach to management of change through intelligent use of business information systems" (contracting body: TUC);
4. external evaluation implementation of the Action 20 of the Activity 3 project ARTEMIS: EQUALITY IN ARMED FORCES "European Project EQUAL" (contracting body: Research Center, University of Piraeus).

CONCLUSIONS

As obvious from its activities, HELORS is an active organization and based on its members' quality, tries to achieve its objectives and increase leverage.

In upcoming years, high priority will be given to collaborations with several scientific unions, such as the Hellenic Mathematical Society, Hellenic Society of Artificial Intelligence, and Greek Computer Society, with an aim to jointly organizing conferences of similar interest.

HELORS intends to organize a student conference in OR in which undergraduate, postgraduate, and doctoral students can present their works and attend lectures from distinguished researchers of this field.

In parallel, it will establish the OR award medals for the best work (undergraduate, graduate, and doctoral); this is aimed at providing motivation for young scientists and researchers to participate in the activities of the HELORS to ensure continuity and proliferation of OR concepts, and will create new incentives for the country's scientific potential.

INTRODUCTION

The US Department of Defense (DoD) employs many models, and these models vary tremendously by type and purpose. The more common types of models used by the DoD include those listed by Gueret *et al.* [1]:

- simulation models;
- optimization or mathematical programming models;
- financial models;
- logistics and inventory models;
- statistical models.

These models span a range of applications such as

- analysis of combat operations;
- analyses of weaponry effectiveness;
- development and analysis of deployment plans;
- programming for and analysis of weapons procurement;
- personnel scheduling;
- logistics forecasting.

An optimization model develops a best allocation of resources, subject to various resource limitations. This optimization process employs some computerized algorithm

that conducts a search among potential solutions to locate some best feasible allocation. This computerized search requires a computational representation of the optimization problem of interest.

A general form of a constrained optimization problem is

$$\begin{array}{ll}\text{Minimize} & f(x) \\ \text{subject to} & x \in \Omega.\end{array}$$

The function $f(x)$ represents some objective or cost function we wish to minimize by finding values for the vector of decision variables, x . These variables x are elements of the space of feasible solutions denoted by Ω . In linear programming, Ω is defined as the intersection of the linear constraints defined for the problem. In nonlinear programming, the definition of Ω may involve nonlinear constraint functions. In integer programming, the continuity of Ω is lost due to integrality constraints placed on some or all of the decision variables. A special case of integrality constraints placed on Ω involve binary restrictions on x ; particular x variables take on values of 0 or 1. Binary programming problems are among the more difficult problems to solve and are thus often solved using heuristic search methods.

Classic optimization algorithms use objective function derivative information to search among feasible solutions (i.e., searches within the feasible region of the problem defined by the problem constraints). These approaches provide guarantees of convergence to global optimal solutions for linear models or local optimal solutions for nonlinear models.

Heuristic optimization algorithms are search procedures based on nonderivative information. These are sometimes called *local search procedures*. With increased computing power, such approaches have become increasingly popular when solving large, complex problems. Although they provide no guarantee of optimality, heuristic solutions

are generally quite good but more importantly, they can accommodate more complex problem formulations than can be accommodated by classical optimization methods.

Our current focus is on the use of heuristic search methods applied to military optimization and modeling problems. We can distinguish heuristic search techniques from classical techniques by the following characteristics:

- They do not guarantee convergence to a global optimal (in general).
- They do not employ gradient-based techniques.
- They involve some form of local neighborhood evaluation.
- They have some analogy to a heuristic problem-solving approach or an analogy to some natural process (that has some optimization aspect).

Despite our focus on heuristic search methods, we must note that there is increased interest in the computational research area in combining classical optimization methods with heuristic search methods. Such hybridized approaches exploit the search properties of heuristic approaches with the focused local search capabilities of classical methods. A thorough discussion of these approaches are a natural extension to this article, but outside its current focus.

The remainder of this article is organized as follows. In the section titled “Heuristic Search Concepts,” we provide a fundamental understanding of important concepts pertaining to heuristic search methods for optimization. These concepts provide a foundation for subsequent sections that overview various heuristic search techniques. Subsequent sections provide overviews of simulated annealing (SA), genetic algorithms (GAs), tabu search, scatter search, ant colony optimization (ACO), and particle swarm optimization (PSO). In each of these sections, we introduce the motivations for the technique, the fundamental concepts pertaining to how the technique functions and, where appropriate, discuss some of the advanced concepts associated with the technique. In the section

titled “Military Applications,” we provide an overview of how some of these heuristic search methods have been applied to various military-focused modeling applications. We end with concluding remarks pertaining to the use of heuristic search methods in military optimization applications.

HEURISTIC SEARCH CONCEPTS

According to Silver [2], “the term heuristic means a method which, on the basis of experience or judgment, seems likely to yield a reasonable solution to a problem, but which cannot be guaranteed to produce the mathematically optimal solution.” The use of heuristic methods is not a new trend. Early research examined a variety of heuristic solution methods for solving hard discrete optimization problems. For example, heuristics such as the Hungarian method, the nearest-neighbor route construction approach, the minimum spanning tree algorithm, or the cost–benefit ratio calculations for knapsack problems are often covered in a basic optimization course. These heuristics select decision variable values that produce an immediate gain based on the current information available to the algorithm. A common label of “greedy” is applied to these approaches. These approaches are greedy in the sense that current decisions are based just on currently available data versus basing those decisions on globally available information.

Unfortunately greedy heuristic approaches sometimes yield poor quality solutions. With a greedy approach, a “good” variable selection earlier in the solution construction process is usually offset with “poor” variable choice later in the process due to the inescapable limitations on variable selections; the greedy approaches suffer from a loss of freedom of choice later in the process. This is referred to as getting “trapped in regions of local optimality” and the regions where the heuristic search is trapped too often contain poor solutions.

Modern heuristics first construct a solution and then improve upon that solution by including mechanisms to escape from

the locally optimal regions. These modern heuristics, many of which were discovered when examining algorithms based on some natural phenomena, are collectively referred to as metaheuristics. According to Osman and Kelly [3], a “metaheuristic is an iterative generation process which guides a subordinate heuristic by combining intelligently different concepts for exploring and exploiting the search spaces using learning strategies to structure information in order to find efficiently near-optimal solutions.” The nature of how the subordinate search is guided, how the solutions are structured, and how the process learns varies by heuristic and specifics of each distinguish the particular metaheuristic. The remainder of this section provides some of the common terminology and concepts underlying metaheuristic search strategies.

Any metaheuristic seeks good *solutions*, x , to the optimization problem. These solutions provide decision variable values that provide the best available solution for some specified evaluation criteria while meeting all restrictions on the solution. All solutions have *attributes*, or characteristics, that define the solution. For instance, in routing problems, typical attributes are the number of routes, number of vehicles, the customers assigned to each route, and the order in which the customers are visited within each route. In assignment problems, attributes might be how jobs are assigned to workstations, the order of the jobs within the workstations, when jobs need to be completed, how much time jobs require for completion, and when jobs should be completed. The solution *evaluation* is a function that maps the combination of decision variable values to some numerical indicator of quality; for instance, the objective function for the problem. The solution *restrictions* are the constraints on the problem. A metaheuristic systematically searches among problem solutions, moving among those solutions via some *transition function*, $t(x)$. A transition function is defined for the problem and provides the basis for changing a current solution to a new solution, thus constituting a *move* among the solutions in the problem solution space. Metaheuristics exploit this *neighborhood* concept to control

the search. The neighborhood of a solution consists of those solutions obtained using the transition function. An improving search continues to find better solutions through the search process. As the rate of solution improvement drops, the search is said to have slowed. When search improvement stops, the search is said to have stagnated, stabilized or in some cases, to have converged.

The general approach for a heuristic search algorithm is the following:

1. Initialize any search parameters; generate an initial solution or set of solutions.
2. Generate the neighborhood of the solution, denote this as $N(x)$.
3. Evaluate members of the neighborhood.
4. Select some best element of the neighborhood.
5. Set the new solution to the best element by transitioning from the current solution to the new solution.
6. If not done searching, go to Step 2, else return current best-found solution as final solution.

The general approach described above is more specific in actual practice and varies by algorithm. Some approaches may vary how the initial solutions are generated or may periodically reinitialize the search. Some algorithms change the definition of the neighborhood especially during the execution of the algorithm. Muller-Merbach [4] describes various search neighborhoods. Evaluation of the members of a neighborhood can be a computationally expensive process, therefore some algorithms employ strategies to reduce the neighborhood evaluation effort. Examples of neighborhood strategies include the following:

- evaluate all members and choose the best;
- evaluate members until the first feasible solution is found;
- evaluate members until a first improving solution is found;

- evaluate a subset of members choosing the best in the subset;
- evaluate and use some randomly chosen member.

Some heuristic implementations employ data structures to store a set of best solutions found during the search. For instance, this set of best solutions found can be used to restart the search process, provide a range of potentially good solutions, or provide the best solution found by the heuristic search algorithm.

A defining aspect of modern heuristic search algorithms is their use of an explicit strategy to escape regions of local optimality. Classic methods, such as linear programming, gradient descent (or ascent) for nonlinear problems, even greedy heuristic search algorithms stop when there are no improving moves. In the case of linear programming, the solution returned is optimal. In the case of nonlinear problems, the solution returned is a local optimal. For greedy heuristic search algorithms, lack of an improving move stops the process and the process is deemed to be at a local optimal (albeit sometimes not a very good solution in terms of global optimality). The power of modern heuristic search algorithms is their ability to escape these regions of local optima and continue transversing the search space. Some of the more common escape mechanisms include

- acceptance of nonimproving moves as a means to transition the search out of the local optima regions;
- restarting of the search from a predefined set of solutions or from a newly generated solution;
- generation of and transition to some new random solution;
- modification of the transition function such as in variable neighborhood search strategies found in routing strategies [5].

We close this background section with definitions of other terms commonly found in the heuristic search literature. First, *diversification* within a search algorithm means moving

into new, potentially unexplored regions of the search space. Diversification is used to expand the search and ensure more thorough coverage of the solution space. Strategies employed for diversification vary by the algorithm considered. Conversely, *intensification* within a search algorithm refers to a reinforcement of the local improvement strategies to move toward locally optimal solutions. Intensification is a focusing of the search effort to hone in on some local optimal point. The more strategic search algorithms incorporate both mechanisms transitioning between periods of intensification and periods of diversification.

The concept of *learning* is often used in the discussion of a heuristic search algorithm. In general, learning entails using search history to tune the search based on the results of the search. In some algorithms, for instance SA and GAs, these learning mechanisms might involve changes to the search parameters. In other algorithms, like tabu search or scatter search, these mechanisms might involve the strategic use of data structures to store information regarding search progress and then using that data, the *memory* of the search, to modify specific aspects of the search. Finally, a *dynamic* search algorithm can change or adapt search parameters during the search to make it more productive and efficient.

SIMULATED ANNEALING

Background and Motivation

SA is one of the earliest search heuristics for optimization inspired by a natural analogy. The analogy is “to the process of physical annealing with solids, in which a material is heated and then allowed to cool very slowly until it achieves its most regular possible crystalline state, with corresponding minimum energy” [6].

As discussed in Kirkpatrick *et al.* [7], Metropolis *et al.* [8] first introduced a computational form of SA as a means to simulate “a collection of atoms at equilibrium at a given temperature.” The Metropolis approach involved the probabilistic acceptance of nonimproving steps of a process. In their case, when an atom is displaced causing a decrease in

system energy, the displacement is accepted and the simulation proceeds. If the energy is increased, then the displacement can be rejected with some probability. That probability function involves a parameter called the *temperature*. This temperature parameter decreases during the execution of the algorithm, causing changes to the probability of accepting the nonimproving moves.

Kirkpatrick *et al.* [7] tied the Metropolis algorithm to optimization and demonstrated the algorithm on various optimization problems.

The Algorithm

SA is a local search algorithm with a probabilistic element that provides the SA with an escape mechanism to depart from the local optima region. Early in the search, random moves are generally accepted. As the search progresses, nonimproving random moves are accepted less frequently. Early search processes promote diversification, later search processes promote intensification.

The SA search process, assuming we want to find a maximum value, is as follows:

1. Initialize the search process:
 - set initial solution x_0 via some selected method;
 - set temperature reduction factor, $0 < \alpha < 1$, initial temperature, f_0 , and $f_{\min}$ as minimum temperature;
 - set $nreps$ as maximum iterations per temperature and $reps = 0$ as current iteration counter;
 - set $x = x_0$ and $f = f_0$ as initial solution and initial temperature, respectively;
 - determine neighborhood of any solution, $N(x, t)$.
2. Randomly select $x^0 \in N(x, t)$. Increment $reps$.
3. Calculate $\delta = f(x) - f(x^0)$.
4. If $\delta < 0$ then set $x = x^0$, else generate $u \in U(0, 1)$ and then, if $u < \exp(-\delta/f)$, $x = x^0$.
5. If $reps \leq nreps$, go to Step 2.
6. Set $f = \alpha f$, $reps = 0$. If $f \geq f_{\min}$, go to Step 2, else Return x as final solution.

In Step 2, the transition function randomly selects a neighbor of the current solution x . The change in solution is calculated in Step 3. In Step 4, improving solutions are always accepted while nonimproving solutions are selected with probability that is a function of the current temperature, f . When the temperature is high, such as early in the search process, the probability of selection is higher giving diversifying activity to the search. As the temperature decreases, the probability of selection decreases giving intensifying activity to the search. At high temperatures the SA algorithm resembles a random search while at low temperatures the SA algorithm resembles an ascent function (again, assuming maximization is the objective). The $nreps$ parameter provides the number of iterations at each temperature level (Step 5). In Step 6, the temperature is lowered by the factor α . When α is high, the process mimics slow cooling while when α is low, it mimics rapid cooling. When the temperature reaches some predefined minimum, $f_{\min}$, the SA process stops and returns the current solution, x .

The SA algorithm requires problem-specific decisions prior to implementation and execution. These decisions are

- a formulation of the problem,
- a neighborhood definition and transition function,
- an objective function,
- a strategy for handling any problem constraints,
- some procedure for obtaining an initial solution.

The SA can actually be thought of as a set of algorithms, each distinguished by the parameter values assigned. These more generic algorithm-specifying decisions include setting the values for α , f_0 , $f_{\min}$, and $nreps$. Unfortunately, few guidelines exist for setting these parameters; generally, the parameter values are empirically tuned on sample problems and then set to the derived best values for solving actual problems.

Algorithm Enhancements

The fundamental trade-off in an SA is the cooling rate, α , and the number of iterations

at each temperature, $nreps$. These together form the *cooling schedule* for the algorithm. Theory suggests using large values of α and large values of $nreps$ but this combination however, can lead to computationally expensive procedures. Practical implementations choose smaller values, in some cases even setting $nreps = 1$, offset by large α values.

Practical SA implementations use data structures to save the best solutions encountered during the search. Upon algorithm completion, the best solution in this list is returned. One SA enhancement is called *reheating*. This involves the resetting of f to a higher temperature to promote additional diversification in the search process.

Additional enhancements are more problem-specific. For instance, transition functions and neighborhoods can be adjusted as a function of temperature to oscillate between periods of diversification or intensification. Restricted neighborhoods can be used to accommodate problem constraints or to improve processing time. Data structures can save the search history and avoid revisiting solutions. Finally, the SA can be hybridized with other search methods such as steepest descent (or ascent) to further improve solutions prior to returning the final solution from the algorithm.

Final Comments

SA is one of the earliest metaheuristics. As such, it has been used in many applications and has achieved success in complex optimization settings. While often viewed as a random search, SA is really a neighborhood search that interweaves varying degrees of random escape mechanisms with local improvement to achieve reasonably good solutions to hard (discrete) optimization problems.

GENETIC ALGORITHMS

Background and Motivation

GAs are search procedures inspired by biology and the workings of natural selection. The GA name “originates from the analogy between the representation of a complex

structure by means of a vector of components, and the idea, familiar to biologists, of the genetic structure of a chromosome” [9]. In biology, natural selection reinforces characteristics most amenable to a species’ survival. Genes within the chromosomes of the stronger members, corresponding to the more desirable characteristics, pass to subsequent generations through reproduction.

In optimization problems, solutions are considered members of a population. Each member of this population is assigned a value indicative of its strength or quality; for instance, the objective function value or penalized objective function value. A population reproduction process is then used to match current solutions, biased by each solution’s strength, to produce new solutions, or offspring, by pairing up current solutions in the population. Better solutions, or stronger population members, are paired more often and thus provide greater influence on future solutions, or population members, for the next generation. Problem solutions are encoded so that problem characteristics can be passed onto subsequent population members. Starting with a population of solutions and allowing a “survival of the fittest” evolution process to occur over some number of generations produces a final population of strong solutions that ideally contain the optimal solution from within that population. The best such solution is returned as the problem solution.

The Algorithm

A GA requires an encoding of problem solutions. A typical encoding scheme is to represent the solution as a binary stream. This binary stream is referred to as the *chromosome* while sections representing logical components of the solution are called *genes*; for instance, each decision variable is represented by some binary substream (the gene) which when collectively concatenated yields the chromosome. The actual representation of the problem solution is referred to as the *phenotype* while the encoded representation is referred to as the *genotype*. The mapping from phenotype to genotype is problem-specific and user-defined.

Figure 1. Genetic algorithm flowchart.

Each solution has a strength value or *fitness function*. This fitness function, evaluated in the phenotype and associated with the genotype, is exploited during the evolutionary processes within the GA. This fitness function must account for objective function values and solution feasibility; quite often, penalty functions are used to accommodate problem constraints.

The GA is a population-based heuristic. The GA starts with some initial population and evolves that population through subsequent *generations*. Evolutionary processes produce offspring that potentially replace (weaker) individuals in the current population. This is called the GA *birth and death process*. The resulting population dynamics change the makeup of the population with each generation; ideally, each subsequent generation should be stronger than the previous generation. In optimization terms, each new generation should have a higher average value associated with the population members and the “best” member of the population should never be worse than the best member of the previous generations. These are key attributes for a GA. When the average solution value of the generations does not change or the best solution is not replaced for some period, the GA is said to have *converged*. Intuitively, it means

the population is unable to evolve newer, stronger members, and thus the population is unable to evolve a better solution than that which has already been found.

Figure 1 [10] is a general flowchart of a GA.

Three main genetic operators are used in population dynamics: reproduction, crossover, and mutation. Varying probabilities of applying these operators control the speed of convergence of the GA. The crossover and mutation operators must be carefully designed.

Reproduction is a process in which a new population is created by combining individual strings from the present population, according to their fitness function values [11]. Copying strings according to their fitness values means that strings with higher fitness values have a higher probability of contributing one or more offspring for the next generation. This improves the possibility of survival for very strong solutions, an element of immortality to the population member. There are a variety of ways to select population members for reproduction:

- *Random*. Pick two elements of the population randomly and allow these two to serve as parents.

- *Rank*. Rank order population members and pair parents by their ranking.
- *Elitist*. Only choose among the strongest population members to serve as parents.
- *Tournament*. Pick a random subset from the population, put the best of the subset into the pool of parents allowing multiple copies of any population member.
- *Proportional*. Normalize population member fitness functions and randomly pick parents using the normalized fitness as their probability of selection;

allow multiple copies of any population member.

New individuals are created as offspring of two parents via the *crossover* operation. One or more crossover points are selected at random within the chromosome of each parent. The parts that are delimited by the crossover points are then interchanged between the parents. The individuals formed as a result of such an interchange are the offspring [12]. Common types of crossover are depicted in Fig. 2 [10,12]. Burst crossover is another type of crossover where the

Figure 2. Different types of crossover operators: (a) one-point crossover, (b) two-point crossover, and (c) multipoint crossover.

crossover is made at every bit position [13].

The final reproductive operator is the *mutation* operator. Mutations are random changes made to the offspring chromosome. For instance, for a binary encoded chromosome, each bit in the string is examined and with some small probability, its value is complemented. Mutation provides an element of diversification in the GA plus serves the important task of restoring potentially good solution characteristics that might otherwise get lost during reproduction.

There are a variety of choices in terms of how generations evolve. The production of offspring expands the size of the population, or the current generation. A GA normally retains a constant population size, thus some of this expanded population must be removed, or killed off, to restore the population to its proper size. Once restored, the resulting population represents the next generation of the GA. Three replacement strategies are

- generational, where the offspring replace parents yielding a new population;
- incremental, where proportionally select members for the next generation from the current, expanded population;
- best, where only the strongest members of the expanded population is kept.

The GA continues for some defined number of generations, or until convergence of the population is recognized. The best solution in the population is returned as the estimated “optimal” solution to the problem.

Algorithm Enhancements

There have been a variety of enhancements to the basic GA described above. Only some of those enhancements are discussed here. More complete information can be found in the various texts available on GAs. The interested reader is also directed to Illinois Genetic Algorithms Laboratory, <http://www.illgal.uiuc.edu/web/>, for some of the latest developments in GAs.

GA improvements involve relaxing the underlying natural analogy. The first such

improvement ensures the best member, or members, of a population survive into the next generation. Increasing the mutation rate helps diversify a stagnated search. Reinitializing the population provides a means to restart the research. Expanding the population size for some period of time is another way to increase diversity. Changes to population dynamics operators include using more intricate crossover patterns, fixing certain sections of chromosomes to not allow their destruction during crossover, and ensuring that offspring are feasible solutions.

The reproduction process is sometimes improved. For instance, one adjustment to a GA is to ensure all population members are unique. A *Lamarchian* process takes a solution from the population, applies a local search heuristic to that solution, and if the solution is improved, replaces that solution in the population with the improved solution. This can be applied to multiple members of the population.

Finally, there are also ways to improve the initial population. Elements of a randomly selected population can be improved via local improvement heuristics. A randomly selected population can be improved by intelligently modifying the probabilities associated with the solution selection process [14]. The initial population can also be seeded with strong solutions found via other optimization methods or via specific domain knowledge about the problem. Typically, the stronger the initial population of a GA, the quicker that GA can converge and return its recommended solution.

Final Comments

The GA is a popular metaheuristic solution approach. Because the GA works on an encoded version of the optimization problem, the algorithm is applicable to a wide variety of problems; once encoded with a suitable fitness function, the GA is quite problem-independent. As a result, the GA is arguably the most general-purpose metaheuristic and also arguably one of the two most popular metaheuristics in terms of use and implementation.

The GA does have distracting elements. Some, such as Ross [15] view the GA as an

inferior approach. Since the GA works on a population of solutions, each of which require evaluation, the computational overhead can be troublesome. In some applications, non-binary encoding schemes are required and crossover operations require a good deal of problem-specific knowledge. In such cases, the GA label may be inappropriate. The GA can also experience convergence problems when later generations become “too similar” to effectively produce strong, new solutions. As with most metaheuristics, the GA employs algorithm parameters that may need tuning to work effectively on the problem at hand. This requires additional investigation before one can actually solve the problem of interest. Finally, understanding the schema theory, Reeves [16] proposed that GA performance is most likely not suitable for casual reading.

Additional details can be found in the work of Beasley *et al.* [17,18], the article by Reeves [19], and the overview chapter by Reeves [9].

TABU SEARCH

Background and Motivation

Tabu search’s analogy is to mimic the human problem-solving process. These approaches involve the use of memory to help avoid repeating self-defeating sequences and the search approach when the current search strategy stagnates.

The Algorithm

Fundamentally, tabu search is a local search procedure but it is augmented by additional rules to provide additional search capabilities. The fundamental approach within local search is to examine the neighborhood of the current solution (which includes evaluation of those neighbors), select some neighboring solution, transition to that neighboring solution, and repeat the process until some termination criteria is met. This simplistic approach however has issues associated with cycling among solutions and getting stuck in regions of the solution space.

The tabu search framework introduced the concept of the *tabu list*, a data structure of solution attributes deemed “off limits” for some number of search moves (called their

tabu tenure). Ignoring tabu attributes causes good features to remain in solutions, or out of solutions, and provides a mechanism to allow the search to move out of regions of local optimality. Use of multiple tabu lists is sometimes used to further enrich the search process.

The *aspiration criteria* allows the search process to override tabu restrictions and visit strong solutions examined within the current neighborhood that might otherwise be ignored. As with tabu lists, multiple aspiration criteria can be employed during a tabu search process. This criteria ensures that good solutions are not ignored during the search.

In a 1977 paper, Glover [20], inspired by Senju and Toyoda [21], introduced the concept of *strategic oscillation*. Strategic oscillation allows a search process to systematically cross barriers other search approaches strictly apply. The most common barrier for Integer Programming (IP) problems is feasibility, either feasibility due to the constraints or feasibility due to the integrality restrictions. A systematic path through the infeasible region coupled with a search path back into the feasible region can compel the tabu search to reach new, potentially favorable regions of the search space.

The basic tabu search framework can be summarized as follows:

1. Initialize.
 - Determine the search neighborhood(s) and solution-evaluation criteria.
 - Define tabu list(s) structure(s) and processes.
 - Define aspiration criteria and memory structures to employ.
 - Create initial solution to problem.
2. Local search. Examine and evaluate neighboring solutions. Select best non-tabu neighbor or best tabu neighbor that meets aspiration criteria.
3. Implement move to the selected neighbor. Update tabu list structures (and other memory structures used). Return to Step 2 if stopping conditions are not met.
4. Return best solution found.

The basic tabu structure outlined above can be expanded to include predefined strategic oscillation phases. This structure can also involve dynamic aspects. Battiti and Techionli [22] dynamically change the tabu tenure employed, based on recorded search progress. In their reactive tabu search, if memory structures indicate the search progress has slowed or is cycling among sequences of solutions, the tabu tenure is (temporarily) adjusted to diversify the search.

Algorithm Enhancements

The basic tabu search outlined above provides a flexible, robust, and generally effective search process. However, on more difficult problems, additional structure can be exploited to try and improve the solution returned from the basic tabu search. Within the tabu search framework, these additional structures are referred to as *intermediate* and *long-term memory approaches*.

Intermediate-Term Memory Approaches. The key component of intermediate-term memory is the *elite list*. This list contains good solutions encountered during the search process. For example, the list may contain good neighbors evaluated but not selected for a move during the basic tabu search process. Kinney *et al.* [23] build an elite list via a variety of solution construction methods for routing problems.

When invoked during the tabu search process, intermediate-term memory search efforts will extract a solution from the elite list and restart the tabu search from that solution. This restart process may or may not alter the current status of any memory structures to tabu lists; this is a strategic choice made by the tabu search designer. The extraction and restart process continues using elements from the elite list for a predetermined period of time or until the elite list is exhausted.

Placing solutions on the elite list is tabu search specific; the search design process determines the membership criteria. Examples of criteria include: solution is some percentage of overall best solution, some percentage from best solution in the current neighborhood, or is among some set of top

solutions in the neighborhood. Use of the elite list diversifies the search into new regions and intensifies the search by using good solutions from the elite list to restart the search process.

Long-Term Memory Approaches. The long-term memory aspects of tabu search are intended to radically diversify the search and involves processes that can be fairly complex. The long-term memory aspects of the tabu search framework are unique in the realm of heuristic search methods.

The *vocabulary building* process involves the structured use of memory to build new solutions from which the tabu search process can restart. During the search process, as moves are implemented, a catalog of solution attributes can be maintained. This catalog is then accessed at some point during the search process to ascertain attributes often used and attributes infrequently used in solutions. Such attributes are then combined to create new solutions. For instance, using infrequently found attributes can yield a new solution. The solution might be of poor quality but may be so diverse a solution that it places the tabu search process into a new region of the search space, a region that may have really good solutions within it. Combining frequently used attributes may yield a very strong solution. Sometimes the solution may be infeasible but may yield a search trajectory back to the feasible region and into a new region of the search space. Building such tabu search implementations requires consideration of attribute data structures, updates to these data structures, and mechanisms to use the data structures.

Path relinking involves the use of good solutions and a constructed search along a path connecting the two solutions. This involves a problem-specific routine that transforms one target solution to another target solution via a sequence of attribute changes. One rationale for the path relinking approach is that better solutions may lie between good solutions and local search mechanisms may be unable to follow the path between the good solutions using just the defined neighborhood search functions; the path must be forced by the search process.

Controlled randomization can come into play in the tabu search framework and this involves modifying the search neighborhood such that some set of good solutions, from the current neighborhood, are selected and then one of the elements from this set are picked probabilistically. For instance, the approach may be to take the top five neighbors of a current solution. The probability of selection among any of the five neighbors is then a function of their solution quality (i.e., objective function value). The stronger neighbors thus have a better chance of selection. The random component adds an extra element of diversity to the search process.

Each of the above long-term memory strategies are evoked based on triggering rules embedded within the tabu search process. Such rules generally emanate from a *target analysis* effort performed on the problem type. Target analysis is a key learning process of tabu search. It involves a systematic off-line study of solution search performance, a conjecture regarding new search rules, and experimentation to support or reject the conjecture regarding the candidate rule. Effective search rules are subsequently embedded into the tabu search framework for use on general instances of the problem.

Final Comments

Tabu search features three key themes [24]:

1. flexible memory structures;
2. a mechanism to control the freeing and constraining of the search process;
3. memory structures of differing time spans to promote intensification and diversification.

The resulting framework of tabu search provides a flexible, powerful mechanism for solving IP problems of varying complexity. The flexibility of the framework has yielded a variety of innovative optimization search processes. Each of these search processes feature the interplay between intensification of the search in promising areas of the search space and then diversification of the search into new regions of the search space when the search process is deemed to have slowed or even to have stalled.

Details of the tabu search framework are plentiful. However, the interested reader can find the key insights in Glover's work [24–26], the text by Glover and Laguna [27], and the chapter by Reeves [9].

SCATTER SEARCH

Background and Motivation

Scatter search was first proposed by Glover in a 1977 paper [20] and hit its stride in 1990 [28]. The motivation for the concept came from formulations that obtained solutions by combining decision rules and constraints (see work by Laguna and Marti [28] or Glover *et al.* [29] for details).

Another way to consider scatter search is to assume that given some set of good solutions to a problem, potentially better solutions may exist in the subspaces spanned by subsets of these good solutions. In a simple example, given two good solutions, x^1 and x^2 , consider potential solutions on the line containing both x^1 and x^2 . Scatter search is sometimes related to the concepts found in simplex search.

The Algorithm

The basic scatter search template has five methods [28].

The *diversification method* is defined as a way to generate a fairly large set of trial solutions. Typically, some seed solution is generated and the diversification method is used to create the trial pool of solutions with sufficient diversity to adequately cover the solution space.

An *improvement method* is used to transform some trial solution into an enhanced (i.e., better) solution. This method varies by problem type.

A *reference set update method* maintains some “best” set of solutions of high quality and sufficient diversity. This best set is called the *reference set*.

A *subset generation method* extracts members of the reference set to create new combined solutions for the problem of interest.

A *solution combination method* uses the results from the reference set to create the combined solutions.

These template methods are used to create the specific scatter search implementation. The generic scatter search process is defined as the following four step process:

- Step 1. Generate starting set of solutions; improve solutions; extract reference set.
- Step 2. Create new pool of solutions via solutions combination method.
- Step 3. Attempt to improve the solutions in the new pool using the improvement method.
- Step 4. Update reference set with best solutions from the improved pool. Return to Step 2 until stopping condition is met.

Upon completion, the final reference contains the best solution found by the algorithm. Additionally, a dedicated memory structure can be employed to specifically retain the best or set of best solutions encountered during the search process.

Algorithm Enhancements

While the basic scatter search is quite flexible, additional features have been added to improve the power of the algorithm, particularly when used on difficult problems.

The basic scatter search employs a static method for reference set updating. This static approach examines all combinations from the reference set to create the trial pool from which the reference set is updated. A dynamic update method puts quality trial solutions into the reference set and makes those new reference set members available for the combination method. This quickly removes poor solutions from the reference set and gets the better solutions involved in the search process sooner.

When scatter search progress slows, the reference set can be rebuilt. One way to rebuild the reference set is to create a new reference set with maximally diverse solutions [30].

The reference set can be tiered to avoid search stagnation. While the reference set is generally updated based on solution quality, a two-tier reference set would add updates

based on solution diversity as well. Thus, the reference set will use both, high quality solutions and diverse solutions in the combination generation method. This helps keep the search aggressive (with the high quality solutions) and productive (with the diverse solutions).

Combination methods typically consider reference set solutions in pairs. Advanced combination methods employ three or more reference set members to create a new combination. This use of multiple members, when coupled with improved combination methods, provides tremendous diversification capability for the scatter search process.

Finally, memory structures can enhance the search. Hashing functions can be used to store all solutions encountered during the search, thereby avoiding the reexamination of solutions. Attributes of solutions can be tracked using data structures and the information exploited to generate diverse solutions or to intensify the search. Such strategic uses of memory are influenced by the success of these approaches in tabu search.

Final Comments

Scatter search is a relatively new meta-heuristic search technique. However, scatter search is easily hybridized with other methods, making the approach quite flexible. The scatter search technique is also quite apt for simulation optimization applications and is found in the OptQuest optimization package [28].

ANT COLONY OPTIMIZATION

Background and Motivation

Ant colony algorithms are inspired by the foraging behavior of a colony of ants. Despite their lack of communication skills (as we know them), foraging ants demonstrate the ability to collectively find a shortest path route from their nest to a food source. They even demonstrate an ability to adapt their routes when those routes get disrupted.

Ants employ an indirect form of communication wherein ants deposit pheromones along their selected trail [31]. Shorter trails

are transited quicker, and thus more often and so are reinforced with more pheromone deposits influencing other ants to follow those paths. This *stigmergistic* behavior is mimicked in optimization algorithms where the path length is used to reinforce segments selected for a path. The formulation challenge is to characterize the optimization problem as segments over which the “ants” travel.

The Algorithm

The ACO algorithm computationally mimics the environmental reinforcement behavior observed in real ants. The ACO algorithm requires the following elements:

- an optimization problem mapped into a set of nodes, connected via segments that an ant travels over to construct a solution to the problem;
- a means to evaluate the quality of the solution obtained by the ant;
- a data structure used to track the artificial pheromone deposited (and remaining) on each of the problem segments;
- a means for updating the pheromone data structure based on solutions obtained by the ants;
- a transition policy employed by the ants to choose among segments balancing random segment selection, segment selection based on quality of the segment, and segment selection based on pheromone levels.

The ACO is a population-based heuristic; a set of artificial ants are allowed to individually arrive at solutions to the problem. The artificial ants are given memory (to avoid duplicate segment selection) and a look-ahead capability (to select among available segments during solution construction).

Initially, ants move randomly through the network of segments. From a given segment, the ant views the remaining segments, picks one at random, and adds that segment to its partial solution. Once all ants have constructed their solutions, the set contains good and poor solutions.

The next step is for each ant to deposit pheromone on the segments used in their

solutions but deposit an amount related to the quality of that ant’s attained solution. One such pheromone deposit function is

$$\Delta\tau_{ij}^k = \begin{cases} \frac{Q}{L_k} & \text{if edge (i,j) used,} \\ 0 & \text{otherwise,} \end{cases}$$

where Q is some user-defined value, L_k is the solution constructed by ant k , and τ_{ij}^k is the pheromone deposited by ant k on segment (i, j) . This pheromone change is coupled with a pheromone decay function so that a typical pheromone update function resembles the following expression:

$$\tau_{ij} = (1 - \rho)\tau_{ij} + \Delta\tau_{ij},$$

$$\Delta\tau_{ij} = \sum_{k=1}^m \tau_{ij}^k.$$

The decay factor, ρ , is used to ensure the segment pheromone level, τ_{ij} , is not reinforced too much and that it loses reinforcement over time. The value $\Delta\tau_{ij}$ is the sum of pheromone deposited by the set of m ants.

Each ACO uses a function to guide the ant’s transition behavior. This transition function provides probability values associated with any available segments biased by both, the heuristic “desirability” of the segment and the segment’s current pheromone level. For instance, Velayudhan *et al.* [32] use

$$p_{ij}^k = \begin{cases} \tau_{ij}^\alpha v_{ij}^\beta / \sum_{\ell \in S} [\tau_{i\ell}^\alpha v_{i\ell}^\beta], & j \in S, \\ 0, & j \notin S, \end{cases}$$

in the context of a traveling salesman problem application. The probability ant k , currently at node i , selects segment (i, j) among their set of possible segments, $j \in S$, is p_{ij}^k . The τ_{ij} is the pheromone level on segment (i, j) , the v_{ij} is a desirability measure of the segment (such as the distance, weight or cost), and the parameters α and β are user-defined and control the influence of pheromone and desirability, respectively, on the transition tendencies of the ant.

The set of ants iterate through some predetermined number of tours, after which the best solution found is returned.

Algorithm Enhancements

The ACO has been applied to many classes of optimization problems. Velayudhan *et al.* [32] have compiled a list of these applications.

A common enhancement to the ACO is to change the pheromone update strategy. For instance, rather than allowing all ants to update, an elitist strategy allows only those ants with good solutions to update the pheromone trail. Another strategy is to always let the best overall solution update its used segments. Both strategies keep selection pressure on those segments associated with the better solutions. Another change is to update pheromones during their tour construction instead of at the completion of all tours.

Influences on the transition function can also be used. Changing the transition function form, that is changing the v_{ij} during algorithm execution, further evaporating τ_{ij} , evaporating the τ_{ij} for the segments (i,j) not used, and modifying the α and β parameters are methods that have been explored. When used, computational study is required to fine-tune the changes to the problem parameters investigated.

The ACO can quickly converge to solutions. The pressure caused by the pheromone update scheme can cause all ants to effectively construct the same solution. Too often, this convergence occurs too early in the search process which can lead to solutions of inferior quality. A common enhancement to promote diversification in the search is to restart the search process, add periods of random solution construction, or drastically change the α and β parameters.

Final Comments

The ACO is a reinforcement learning system. The ACO is sometimes implemented as an agent-based approach and called an *agent-based optimization method*. Despite being relatively new, the ACO algorithm has quickly established credibility in solving hard combinatorial optimization problems. Among its detracting features are its sometimes early convergence characteristics, the computational overhead of a population-based approach, the need for tuning the

parameters of the algorithm, and its sometimes tenuous application to general IP or continuous-variable optimization problems.

For further reading on the ACO, see Dorigo *et al.* [31] and the complete section on the ACO in Corne *et al.* [33].

PARTICLE SWARM OPTIMIZATION

Background and Motivation

PSO is a specific algorithm that is a subset of the class of swarm intelligence algorithms that are based on the collective social behavior of species that compete for food. Ants, bees, fish, termites, and birds are examples of species that exhibit cooperative social behavior by indirect communication, which enables the members of the group to select appropriate movements within a defined search space to look for food [34]. PSO is a stochastic population-based metaheuristic which mimics the behavior of a school of fish or flock of birds in their search for food. The “school or flock” work together by coordinating their movements without any central control. This algorithm is relatively simple to implement and has been shown to be effective on a variety of problem structures. The algorithm is biologically inspired with strong links to evolutionary computation. “This algorithm belongs ideologically to that philosophical school that allows wisdom to emerge rather than trying to impose it, that emulates nature rather than trying to control it, and that seeks to make things simpler rather than more complex” [35].

The Algorithm

In the basic model, we assume we have a flock of birds or school of fish which we represent as N particles. Each particle (bird or fish) is composed of three D -dimensional vectors; the current position $\vec{x}_i$, the previous best position $\vec{p}_i$, and the velocity $\vec{v}_i$, where D is the dimensionality of the search space. Each particle i is a candidate solution to the problem being studied and therefore the objective function is calculated for each particle at its current location. Each particle then determines its movement through

the search space by successively adjusting its position toward the global optimum by combining aspects of its own history and current position with those of other members of the swarm. The next iteration takes place after all particles move to their next position. The selection of the next position is based on two factors: the best position visited by the individual particle $p_i = (p_{i1}, p_{i2}, \dots, p_{iD})$ which we designate $pbest_i$, and the best position visited by the entire swarm, $gbest$ denoted as $p_g = (p_{g1}, p_{g2}, \dots, p_{gD})$. These particles serve as leaders, and assist the search algorithm in finding the better regions of the decision space. New points are selected by adding $\vec{v}_i$, coordinates to the current position, $\vec{x}_i$, where $\vec{v}_i$ serves as the equivalent of a step size for the next move. The velocity, which defines the amount of change that is applied to the current particle position, is updated using the following relation:

$$v_i(t) = v_i(t-1) + \rho_1 C_1 \times (p_i - x_i(t-1)) \\ + \rho_2 C_2 \times (p_g - x_i(t-1)),$$

where ρ_1 and ρ_2 are two uniform random numbers. The constants C_1 and C_2 represent

the cognitive and social learning factors, respectively. The cognitive learning factor represents the attraction a particle has toward its own success, while the social learning factor represents the attraction the particle has toward the success of its neighbors. The elements of $\vec{v}_i$ are ordinarily limited to some defined range, $[-V_{\max}, V_{\max}]$, which has the effect of influencing the balance between exploration and exploitation of the search space. Each particle will then update its coordinate position vector as follows:

$$x_i(t) = x_i(t-1) + v_i(t).$$

Each particle then updates the best local and global solutions, if appropriate, as follows:

$$\text{if } f(x_i) < pbest_i, \text{ then } p_i = x_i. \\ \text{if } f(x_i) < gbest, \text{ then } g_i = x_i.$$

The pseudocode for the PSO algorithm is given below:

Random initialization of the entire swarm;

Repeat

Evaluate $f(x_i)$

For all particles, i

Update velocities:

$$v_i(t) = v_i(t-1) + \rho_1 C_1 \times (p_i - x_i(t-1)) + \rho_2 C_2 \times (p_g - x_i(t-1))$$

Move to the new position: $x_i(t) = x_i(t-1) + v_i(t)$

IF $f(x_i) < pbest_i$, **then** $p_i = x_i$;

IF $f(x_i) < gbest$, **then** $g_i = x_i$;

Update (x_i, v_i) .

EndFor

Until Stopping Criteria

The final issue to resolve is the selection of values for the various parameters in the PSO algorithm. First, one has to decide how many particles (or members of the flock) to have in

the algorithm. The value of N , the number of particles, is inversely related to the number of required iterations for the algorithm. Like any population-based heuristic, increasing

the population size tends to improve results at the expense of more computation time. Talbi [34] recommends using a value between 20 and 60 for N . The acceleration coefficients are generally set at values ≤ 2 .

Algorithm Enhancements

Inertia Weight. An inertia weighting factor, w can be added to the velocity update equation in order to control the impact of the previous velocity on the current one as shown below:

$$v_i(t) = w \times v_i(t-1) + \rho_1 C_1 \times (p_i - x_i(t-1)) \\ + \rho_2 C_2 \times (p_g - x_i(t-1)).$$

The motivation for the inertia weight is to gain better control of the search and reduce the impact the selection of $V_{\max}$ has on the convergence of the algorithm. A large inertia weight encourages global exploration while a smaller inertia weight encourages local exploitation. Researchers have found that that the best performance is obtained by initially setting w to a value of 0.9 and gradually reducing it to a much lower value of about 0.4 as you move toward homing in on the local optimal value.

Constriction Coefficients. The use of a constriction coefficient helps dampen the dynamics of the particles beyond what was capable with the use of $V_{\max}$. Clerc and Kennedy [36] describe many ways to implement constriction coefficients. The simplest method is given as follows:

$$v_i(t) = \chi (v_i(t-1) + \rho_1 C_1 \times (p_i - x_i(t-1)) \\ + \rho_2 C_2 \times (p_g - x_i(t-1)),)$$

where $C = C_1 + C_2 > 4$ and

$$\chi = \frac{2}{C - 2 + \sqrt{C^2 - 4C}}.$$

Using this method, the particles have been found to converge without using any $V_{\max}$. Another approach by Shi and Eberhard [37] recommended using the constriction coefficient approach and limit $V_{\max}$ to $V_{\max}$, which is the dynamic range of each variable

in each dimension. This results in a PSO implementation that has no problem-specific parameters.

Fully Informed Particle Swarm. In the implementations discussed above, the PSO algorithm is constantly making the trade between the amounts of influence the local position has, versus the amount of influence the best particle has on the next move. Kennedy and Mendes [38] developed the fully informed particle swarm (FIPS) approach that allows the velocity update to be influenced by all its neighbors and possibly have negligible influence from its previous success. The velocity update formula for the FIPS implementation is as follows:

$$v_i(t) = \chi \left(v_i(t-1) + \frac{1}{K_i} \sum_{n=1}^{K_i} \rho_1 C \right. \\ \left. \times (p_{nbr_n} - x_i(t-1)) \right),$$

where K_i is the number of neighbors for particle i , and p_{nbr_n} is the best position of i 's n th neighbor. For $K_i = 2$, the velocity is updated using only the particle's current position and neighborhood best.

Final Comments

PSO has been used in a diverse range of application settings. Poli [39] provides a detailed review article that categorizes the large number of recent publications that deal with PSO applications in the IEEE Xplore database. The main PSO application areas include image analysis (7.6%), design and restructuring of electrical loads and networks (7.1%), general control applications (7.0%), antenna design (5.8%), power generation and power systems (5.8%), and scheduling (5.6%) [40]. Approximately 1.3% of the more than 1100 papers published using PSO were in the security and military applications domain. These papers included network security, intrusion detection, cryptography, border security, weapon target assignment, and missile effectiveness optimization. Wang *et al.* [41] have used a modified PSO to

perform unmanned combat aerial vehicle (UCAV) path planning. Foo *et al.* [42] utilized a PSO algorithm in their three-dimensional path planning for an unmanned aerial vehicle (UAV). Cui and Potok [43] have used a PSO social model in their multiagent insurgency warfare simulation.

MILITARY APPLICATIONS

The range of military model applications is quite vast. Battilega and Grange [44] required an entire text to review the diverse range of models then available. However, their review did not even include heuristics as a major technique for military optimization applications [44]. This section thus focuses on heuristic methods applied to military optimization applications. Further, the focus is narrowed to the use of the metaheuristic search techniques previously reviewed.

Assignment Problems

The classic assignment problem uniquely pairs objects from one set with objects from another set, while seeking that assignment that either minimizes some cost function or maximizes some profit function. Extensions add additional conditions on the assignment problem realized as constraints within the model. Military applications of the assignment problem include

- maintenance tasks to maintainers;
- aircrews to aircraft;
- personnel to organizations;
- radio frequencies to user channels;
- weapons to targets;
- supplies to delivery modes.

The weapons assignment model application is crucial to military analyses, from developing requisitions to purchasing the weapons to determining which mode of delivery will be used to employ the weapons. Wacholder [45] used a neural network to solve a nonlinear weapon assignment problem for ballistic missile defense. Green *et al.* [46] use a rounding heuristic to find solutions to the arsenal exchange model (AEM), a

model used to assign nuclear weapons to targets. Their rounding heuristic was shown to outperform the existing AEM assignment heuristic. Cullenbine *et al.* [47] apply reactive tabu search to solve the weapon assignment model (WAM). A WAM solution also involves the assignment of nuclear warheads to targets but those solutions are evaluated with respect to multiple goals the plan should achieve. Their solution approach included tabu search mechanisms for search diversification and was found to yield reasonable solutions faster than the currently existing heuristics. Lee and Su [48] use an ant colony algorithm but augment their algorithm with immunity concepts inspired by Jiao and Wang [49]. Immunity concepts include vaccination and immunity processes. A vaccination process uses problem-specific knowledge to modify specific aspects of the solution to avoid degradations in solution quality. An immunity process ensures weaker solutions are not used to reinforce subsequent solutions. Lee and Su [48] compare their approach to SA and GA approaches on four randomly generated problems.

Blodgett *et al.* [50] provide an interesting application of tabu search to the assignment of naval defense systems against anti-ship missiles. Rather than a simple assignment, which may require replanning once operations commence, the authors develop a decision tree-based solution to account for the probabilistic outcomes that arise in actual operations. The intent is to derive solutions more robust to the uncertainty of combat. Erdem and Ozdemirel [51] apply a GA to a force-versus-force allocation problem. Their problem allocates blue (friendly) force components against red (enemy) force components to achieve defined attrition goals at minimal overall effort. The force components on each side are modeled as heterogeneous and divisible components. The GA employs problem-specific chromosome repair operators to ensure feasibility of population members and it employs a local improvement phase to further improve population members (such as found in memetic algorithm approaches).

Military organizations, particularly those deployed in combat zones, require effective communications for operational success. The

frequency assignment or channel assignment problem assigns frequencies to wireless connections to ensure communication can occur and interference from other frequencies is minimized. Aardal *et al.* [52] provide a thorough survey of solution techniques for these frequency assignment problems. Their review includes classic optimization and heuristic search methods. Heuristic methods found in the literature, and covered in their survey, include greedy algorithms, local search methods, tabu search, SA, GAs, and ant colony algorithms. Lau and Tsang [53] was not included in the survey but present a guided genetic algorithm (GGA). The GGA is devised to retain specific knowledge of solution characteristics of the population members. This knowledge structure is used to modify the reproduction process (crossover and mutation) to reinforce or limit strong or weak solution features, respectively. The results indicate that the GGA provides good solutions, but at higher computational costs as compared to local search procedures.

Routing Problems

A routing problem assigns a sequence of destinations to a vehicle so that some cost function is minimized as the vehicle transits the segments connecting the destinations in the vehicle's route. Military applications of routing include

- routing a UAV or set of UAVs over some set of targets;
- routing a surveillance asset over some search region;
- determining the sequence of stops for a mobility aircraft mission;
- determining how to route a missile or aircraft to a target to avoid threats and obstacles;
- determining how to deliver required supplies from supply locations to destination locations.

The routing problem associated with UAVs has received a great deal of attention. Additional constraints added to these problems include considerations of no-fly

zones, arrival time restrictions, time-over-target restrictions, flight duration considerations, and threats within the route space. Ryan *et al.* [54] examine the UAV routing problem with time windows and time precedence considerations. The authors couple a reactive tabu search route finder with a simulation route evaluator to determine "robust routes." The simulation is used to assess target coverage and travel time considerations using stochastic processes for the threats and the weather. Multiple iterations yield route segment information used to determine those better segments to use within the route. O'Rourke *et al.* [55] build upon the optimization portion of this work, yielding a reactive tabu search that solves a more comprehensive routing problem. Harder *et al.* [56] develop a general-purpose tabu search-based routing solver and apply the tool specifically to UAV routing. The tool consists of an interface by which the user can enter a UAV routing problem and a Java-based solver is used to return potential solutions. A subsequent empirical study involved academic benchmark problems and operationally motivated test instances. An open software version of the solver engine is available as OpenTS. Kinney *et al.* [23] consider a set of local searches, to include tabu search, for quickly solving routing problems, specifically UAV routing problems. This study included analyses regarding when to discontinue local search efforts and return the suggested solution. This quick-running heuristic approach was implemented in the UAV routing framework from Harder *et al.* [56]. Shetty *et al.* [57] recently considered the routing of UCAVs. Their problem considers target priorities, minimum and maximum levels of target damage, payload capacities, and range restrictions. They use tabu search to guide subordinate heuristic-solving aspects of the decomposed problem; their tabu search guides the iterative application of an assignment and a multiple traveling salesman heuristic.

A closely related problem is that of choosing flight paths. This is particularly applicable in mission planning to avoid terrain obstacles or known threats and in search planning. John *et al.* [58] use a GA

to determine a flight route for a regional surveillance problem. The GA incorporates constraints for no-fly zone considerations and was able to obtain reasonable solutions in a fraction of the time required by an IP-based solver. Kierstead and DelBalzo [59] employ a GA to design efficient search paths. While applicable to a variety of military applications, the specific application in this case is the detection of submarines within some enclosed search region.

Packing Problems

A packing problem seeks to place some set of objects within some specified, confined space. Attributes of these objects typically include dimensions and weight, but can expand to include myriad other attributes such as interactions with other objects requiring placement. The confined spaces can be single-dimensional, like a knapsack; two-dimensional, such as floor space on a truck; or three-dimensional, such as a shipping container. Typical packing applications can be found in shipping operations, military deployment load planning or storage facilities.

Packing heuristics have been widely used in mobility planning. Early approaches employed greedy algorithms. Cochard and Yost [60] describe the deployable mobility execution system, an early PC-based aircraft load planning system. The army automated load planning system (AALPS) was another early system and was deployed in 1978 [61]. Each tool provided initial load plans, using greedy construction approaches to accommodate various aircraft loading constraints, and allowed the user to interactively tailor the initial load plans. Heidelberg *et al.* [61] provide an improved two-dimensional packing algorithm for the gross load planning of aircraft.

Gueret *et al.* [1] consider heuristics for loading aircraft. They employ two construction heuristics modified by either of two local search algorithms. The first local search approach systematically changes the order items are loaded onto the aircraft to try and improve the solution. The second local search tries to reduce the number of aircraft

required by attempting to empty a selected aircraft's contents into other aircraft having available capacity. Harwig *et al.* [62] apply tabu search to the two-dimensional packing problem applied to the load planning for mobility operations. This problem arises when planning shipments of material or determining airlift requirements for a planned deployment. This approach could apply to the loading of pallets or the loading of aircraft. Baltacioglu *et al.* [63] develop a heuristic for three-dimensional packing of cargo pallets. Their heuristic mimics how humans create packings for a confined three-dimensional space. Related work includes a tabu search approach in Lodi *et al.* [64], a GA approach in Bortfeldt and Gehring [65], and an SA approach in Faina [66]. Morgan *et al.* [67] consider the problem of determining a mix of space launch vehicles for assigning a set of satellites to those vehicles. Modeled as a bin-packing problem, the authors generated over 3600 test problems, solved each to optimality or an upper bound, and examined how well a local improvement heuristic performed. The local heuristic found best solutions in 43% of the problems and on average came within 3–5% of the best-known solutions for the test problems.

Scheduling and Planning

Scheduling and planning involves the sequencing of tasks and the assignment of resources to the tasks. As tasks are sequenced, start times, finish times, and resource expenditures are compiled and examined to ensure solution feasibility. In some applications, such as aircrew scheduling, the plethora of requirements that must be satisfied makes mathematical programming approaches impractical due to the complexity of the formulation and the time required to obtain the proven optimal solution.

Sklar *et al.* [68] consider the problem of assigning crews to airlift routes to minimize the number of crews required to complete the assigned missions. They employ two constructive heuristics iteratively on decompositions of the problem. In their first heuristic, crews are assigned. These crews are used in the second heuristic to determine flight departure times. The departures are

used to reassign the crews when iterating back to the first heuristic. The process is complete when the entire solution stabilizes or an iteration limit is reached. Combs and Moore [69] apply tabu search to the crew scheduling problem. Their tabu search simultaneously determined crew rotations and crew schedules. The exact optimization method, a set-partitioning problem, was used to perform vocabulary building. Their approach then uses all of the partial crew rotations/schedules as columns of the set-partitioning problem (with tabu search as the column generator). Once the set-partitioning problem is solved, it would improve the best current solution by bring rotations/schedules previously not used into the solution. The improved solutions then become new points from which to restart the tabu search. The algorithm accounts for all crew rest and flight restrictions associated with the mobility air crew schedule. Lambert *et al.* [70] apply tabu search to the strategic airlift problem (SAP). The SAP solutions are

- pair aircraft and deployment requirements;
- determine aircraft missions required;
- time phase the aircraft along the mobility distribution network.

McGinnis *et al.* [71] develop a mathematical model for scheduling training resources associated with army initial entry training. A multiphase heuristic is used to develop a resource schedule, based on the projected trainee arrivals. The heuristic solutions are compared to exact solutions obtained via dynamic programming and are found to fall within 10% of the optimal solution, on average, but at a fraction of the computational time required. Butler *et al.* [72] present an integrated system to support the scheduling of combat engineers. They employ a GA to the task of assigning the combat engineering teams to a variety of combat engineering tasks. The scheduling challenge includes assigning and sequencing combat engineering units with differing capabilities to arrive at an efficient and effective schedule to accomplish the set of tasks. Their discussion includes specifics of

how the GA paradigm was tailored to the combat engineering scheduling problem.

Schlabach *et al.* [73] describe FOX-GA, a GA used to support military maneuver planning. The FOX-GA implementation involves three notable contributions. First, the authors use a fast-running aggregate model to evaluate potential solutions by using the time-consuming war games that are generally used. Such solution-evaluation efficiency is crucial for successful use of a GA. Second, the GA offers the decision maker a set of solutions, with a single solution via math programming or the full population of solutions. Finally, the authors implement niching, a GA strategy to ensure population diversity is maintained during the execution of the algorithm. Maintaining the diversity of the population ensures more efficient sampling of the solution search space.

Imsand *et al.* [74] use a GA to conduct a vulnerability analysis on the commander's analysis and planning simulation (CAPS), which is used for the operational analysis of missile defense systems. The GA was used to determine those factors most influencing the simulation output and thus, affecting the planning effectiveness.

Satellite range scheduling involves the assignment of tracking stations to supported satellites to satisfy requested satellite support. Gooley *et al.* [75] develop a heuristic for the Air Force Satellite Control Network scheduling problem. Their approach is to build an initial schedule and apply a local search involving interchange operators to improve the schedule. Results on an actual test problem were fair but obtained in minutes versus the longer time required by the manual process.

Final Comments

Our application review is by no means comprehensive; it is hopefully representative of how these heuristics are employed. We necessarily excluded from our review the vast material found in conference papers, working papers, technical reports, and graduate research documents. A scan of these materials will find the use of metaheuristics in nearly all types of optimization applications. We also did not address the use of heuristics

within a simulation-based optimization setting. Simulation-based optimization methods often use procedures based on SA, GAs, tabu search or scatter search. These methods are “wrapped” around military models and used to guide those models toward some best set of specified input parameters. For instance, Hill and McIntyre [76] use a GA, and later a scatter search-based technique, to find robust solutions to a multiscenario force planning problem involving a linear mathematical program.

CONCLUDING REMARKS

A variety of trends have encouraged the development and employment of search heuristics for optimization applications. Some of these were mentioned in the preceding sections. Others are discussed in the following paragraphs.

Modern computers are tremendously powerful computational devices. Some of us still remember punch-card computer programming or the initial “personal” computers that ran just on floppy diskettes. Modern computers are fast and have lots of memory. This means we can do more calculations and search among more solutions in less time than ever before. Modern computers make heuristic search methods feasible and practical.

Modern problems are very complex. This is not to say that past problems were not complex. In fact past problems were also complex but analytical methods of the time required we simplify these complex problems to accommodate the limited analytical methods. Our modern ability to solve large problems means we sometimes no longer want to simplify reality for the sake of an algorithm. We no longer always want exact solutions to approximations of the true system of interest. We now are often more satisfied with approximate solutions to problems that are more accurate reflections of the system of interest. These more accurate problems often create intractable formulations for classical solution methods. Current decision support requirements for problem solutions make heuristic search methods preferable.

The modern decision-making environment is too fast-paced to wait for a perfect answer (i.e., a guaranteed optimal answer). Getting that guaranteed optimal solution can sometimes take an inordinate amount of time. Getting an answer pretty close to an optimal can now be provided rapidly. These good, feasible solutions can be worth more to the decision maker in time-sensitive, decision-making situations. The pace of modern decision making has thus made heuristic search methods an attractive problem-solving methodology.

To close, the reader should not believe we advocate exclusive use of heuristic search methods for optimization applications; we do not. When practical and appropriate, mathematical programming methods should be preferred and exploited. However, we have hopefully provided the reader with the rationale, background, and motivation to appreciate the valuable role heuristic search methods can serve in an optimization model-based decision-making setting. When practical and appropriate, heuristic search methods should be explored, examined, and employed.

HEURISTICS FOR THE TRAVELING SALESMAN PROBLEM

MARY E. KURZ

Department of Industrial Engineering,
Clemson University, Clemson, South
Carolina

INTRODUCTION

In the context of this article, we consider a *heuristic* to be a method to construct a feasible solution to a TSP instance. TSP heuristics can be considered to be one of three types: constructive, improvement, or composite. We specifically do not include *metaheuristics* in our discussion, though one might consider them to be improvement heuristics. Composite TSP heuristics use a constructive heuristic followed by an improvement phase, so this article does not explicitly consider composite heuristics.

We define a TSP instance by n , the number of cities, and a distance matrix $\mathbf{D}$, whose entries d_{ij} represent the distance associated with traveling directly from city i to city j . Every nondiagonal entry in $\mathbf{D}$ is assumed to exist. Unless otherwise noted, the distance matrix $\mathbf{D}$ is assumed to be asymmetric, non-Euclidean, and not to satisfy the triangle inequality. The interested reader is encouraged to consult one or more of the comprehensive surveys of TSP heuristics, including Refs 1–5. Laporte [6] very recently provided an aptly named concise guide to the TSP, including key results about heuristics for both symmetric and asymmetric TSPs and an extensive bibliography. Emphasis is placed in this article on the most referenced or enduring techniques, rather than providing a historical view of the development of these heuristics. Furthermore, heuristics for the plethora of TSP variants, such as the generalized TSP, are not considered here. References [1–6] also contain extensive computational results, while Bentley [7] details fast implementations of several methods.

CONSTRUCTION HEURISTICS

Construction heuristics iteratively build one feasible solution through the application of a deterministic set of steps. A random permutation of cities can create an initial solution as well. Following the detailed exposition by Reinelt [8], the construction heuristics are divided into nearest neighbor heuristic, insertion heuristics, spanning tree-based heuristics, and savings heuristics. We then consider heuristics explicitly developed for the asymmetric TSP.

Nearest Neighbor Heuristic

Nearest-neighbor heuristics build a solution directly by adding cities to the end of a partial solution. Nearest-neighbor heuristics on a set N of cities have the following basic steps:

1. select a starting city, j . $N = N \setminus \{j\}$;
2. as long as N is not empty,
 - a. select the next city $i : i = \arg \min_N (d_{ji})$;
 - b. append i to the end of the partial solution;
 - c. $N = N \setminus \{i\}$.

The nearest-neighbor heuristic is an $O(n^2)$ algorithm with an arbitrarily poor performance [1,8].

Insertion Heuristics

Insertion heuristics build a solution directly by inserting cities one at a time *into* a partial solution, as opposed to the end of a partial solution. Insertion heuristics vary in their criteria for selecting the next city and determining the position for this city. These two steps are usually considered in tandem, meaning that the determination of *which* city is to be inserted depends on *where* in the partial solution the city is to be inserted. We assume that the city is to be inserted at the location that minimally increases the partial solution total distance, unless otherwise noted. Let the set of cities in any partial solution be called *solution cities*, represented by P .

Basic Insertion Heuristics. The basic insertion heuristics on a set N of cities have the following basic steps, assuming starting with an empty partial solution:

1. select a starting city, j . $N = N \setminus \{j\}$;
2. as long as N is not empty,
 - a. select the next city i ;
 - b. insert i into the partial solution;
 - c. $N = N \setminus \{i\}$.

Selection and Insertion Criteria. Several criteria are summarized [1,8,9] for application in the basic insertion heuristics; no doubt, several more could be conceived. A subset is included as follows:

- *Nearest insertion*—inserts the city that has the shortest distance to a solution city: $i = \arg \min_N (d_{ji} | j \in P)$.
- *Farthest insertion*—inserts the city that has the longest distance to a solution city: $i = \arg \max_N (d_{ji} | j \in P)$.
- *Cheapest insertion*—inserts the city that increases the total length of the partial solution with its inclusion the least.
- *Random insertion*—inserts a randomly selected city.

In general, these criteria, when used with basic insertion heuristics, result in $O(n^2)$ methods [except for cheapest insertion, which can be $O(n^2 \log n)$] [8].

Minimum Spanning Tree Heuristics

If the distance matrix $\mathbf{D}$ satisfies the triangle inequality and is symmetric, then two methods based on the concepts of minimum spanning trees can be used to find a feasible solution to the TSP. We let a graph G represent the distance matrix, so that each node is a city and each edge in G has the corresponding distance from $\mathbf{D}$. The interested reader should also reference material on Basic notation and graph theory concepts.

The Doubling method can be summarized as follows:

1. compute a minimum spanning tree of the graph G and call it M ;

2. double every edge of M , yielding an Eulerian graph called E ;
3. find an Eulerian trail of E ;
4. find a Hamiltonian cycle of E .

The Christofides method differs from the Doubling method in step 2. Christofides suggested finding a minimum weight perfect matching, W , of the odd-degree nodes in M . Then $W + M$, formed by adding the edges in W to M , is an Eulerian graph. The Doubling and Christofides methods are the primary construction heuristics for the TSP with a distance matrix that is symmetric and satisfies the triangle inequality presented in Papadimitriou and Steiglitz [10].

The Doubling method has a running time of n^2 but a worse case bound of two times the optimal tour length. The Christofides method has a running time of n^4 or n^3 (depending on the implementation of the minimum weight perfect matching) and a worst case bound of 1.5 times the optimal tour length [10].

Savings Heuristic

Two comparative studies of heuristics [1,8] found that the Savings Heuristic, also known as the *Clarke and Wright savings heuristic*, performed quite well. The savings heuristic was developed for the vehicle routing problem and adapted to the TSP by Golden [1,8]. The savings heuristic requires the following steps:

1. select a starting city, b . $N = N \setminus \{b\}$;
2. compute the savings $s_{ij} = d_{bi} + d_{bj} - d_{ij}$, for $i, j \in N$;
3. sort the list of savings in descending order;
4. in the order of the sorted savings list, link the edges i and j until a single feasible solution is formed.

On the basis of the definition of the savings, it is presumed that a symmetric distance matrix is required.

A Construction Heuristic for Asymmetric TSP

Laporte [6] identifies the Karp Patch heuristic as being best in its class. In this method, an assignment problem is created using the

distance matrix **D**. If the optimal solution to the assignment problem is not a feasible TSP solution, corrections are made in a process called *patching*. The steps as described in Ref. 11 are as follows:

1. create and solve the related assignment problem. If a feasible TSP solution is found, stop;
2. otherwise, while a feasible TSP solution does not exist,
 - a. select the two cycles with the most cities;
 - b. intelligently combine them by deleting one arc in each cycle and connecting the cycles with arcs between them.

IMPROVEMENT HEURISTICS

Improvement heuristics assume the existence of a feasible solution to the TSP, created in some manner. Improvement heuristics may be good additions to metaheuristic techniques for the TSP (see the articles titled **Guided Local Search**, **Evolutionary Algorithms**, **Ant Colony Optimization**, **Memetic Algorithms**, **Genetic Algorithms**, **Simulated Annealing** in this encyclopedia), providing neighborhoods for local search techniques.

Basic Improvement Methods

Though not often reported in research, simple improvement methods may be desirable for use in metaheuristic approaches due to their speed. These two methods are described in Ref. 12.

The node insertion heuristic considers moving a city from its current location to a different location. The detailed steps can be described as follows:

1. Let T be a current feasible solution.
2. Until $done = \text{TRUE}$,
 - a. For each city $i \in N$: Consider moving city i to all possible other locations in the tour. If the best new location reduces the current tour length, move city i to that location.

- b. If no potential moves for any city provide improvement, set $done = \text{TRUE}$.

The edge insertion heuristic considers moving an edge from its current location to a different location. We could interpret this as moving two adjacent cities from their current location to a new location. The detailed steps can be described as follows:

1. Let T be a current feasible solution;
2. Until $done = \text{TRUE}$,
 - a. For each city $i \in N$: Let $j =$ the city following i in T . Consider moving cities i and j to all possible other locations in the tour. If the best new location reduces the current tour length, move cities i and j to that location by resetting T .
 - b. If no potential moves for any pairs of adjacent cities provide improvement, set $done = \text{TRUE}$.

Reinelt [12] provides computational analysis of the effectiveness of these methods in improving solutions developed with random, nearest neighbor, and savings heuristics, reporting that they are very slow and perform poorly on randomly generated initial tours. However, these form the basis of understanding the Edge Exchange methods below.

Edge Exchange Methods: 2-opt, 3-opt, Lin-Kernighan

Extending the idea of moving one edge from one location to another, edge exchange methods are built on the idea of deleting some number of edges and reattaching the remaining tour sections in a feasible manner.

The most basic of these exchange methods, 2-opt, involves deleting two edges, say (i,j) and (k,l) . Assuming that cities i,j,k , and l appear in this order in the current tour T , then the only way to reconnect them is with the edges (i,k) and (j,l) , with the cities between j and k being reversed in the new tour T' . In fact, Croes called this concept *inversion* [13]. Lin [14] generalized these ideas with the concept of λ -optimality, which is the dominant feature in good improvement methods for the TSP. A tour is λ -optimal if

Figure 1. A feasible eight-city tour.

Figure 2. After a node insertion.

any sets of λ edges do not exist that can be replaced by another set of λ edges, reducing the total tour length. Unfortunately, the concept of λ -optimality and the methods deriving from the idea of λ -optimality are both called by some variant of “ λ -opt”. These statements illustrate the two usages of the phrase: (i) “The tour is 3-opt”; (ii) “I applied 2-opt to the problem.” The reader should use care when interpreting these terms. Golden [9] observes that a λ -opt heuristic is an $O(n^\lambda)$ method.

Figure 1 is a feasible tour of eight cities labeled A to H that are used to illustrate some concepts of the edge exchange methods. We can refer to tour as a list of the cities, arbitrarily beginning with A: ABCDEFGH. The figure provides directional information for the tour through the explicitly included arrows on the arcs.

2-opt Heuristic. 2-opt, as a heuristic, can be implemented as follows [12]:

1. Let T be a current feasible solution;
2. Until $done = \text{TRUE}$,
 - a. For each city $i \in N$: Let j = the city following i in T . Consider exchanging cities i and j with all other pairs of cities k and l in the tour. If the best exchange (say with k^* and l^*) reduces the current tour length, reset T as follows: (i) delete the edges (i,j) and (k^*,l^*) ; (ii) insert the edges (i,k^*) and (j,l^*) ; (iii) reverse the cities between j and k ;
 - b. If no potential exchanges provide improvement, set $done = \text{TRUE}$.

The resulting tour is said to be 2-optimal.

Note that the node insertion local search is a special case of the 2-opt, in which k is the city following j in T . Figure 2 shows how the tour ABCDEFGH can be transformed through a node insertion; specifically, node B is inserted between nodes C and D, resulting in the tour ACBDEFGH. Note that arcs AB and CD have been removed, arcs AC and BD have been added, and the arc BC is now inverted to be arc CB. In general, 2-opt need not invert only a single arc, as illustrated in Fig. 3. Figure 3 shows how a general 2-opt move may be performed on the tour in Fig. 1. Edges CD and GH are removed and edges CG and DH are added. Moreover, edges DE, EF, and FG are now inverted.

3-opt Heuristic. The definition of k -optimality implies the creation of $n - 1$ possible heuristics. On the basis of the computational complexity, each increase in

Figure 3. After a 2-opt move.

k significantly increases the computational complexity. 3-opt is the largest version that is commonly seen. The intent is to find triples of edges that should be deleted and replaced with three new edges, while maintaining a feasible solution. Lin [14] notes that this is conceptually equivalent to identifying a set of cities to be removed from their current location (breaking two edges), possibly inverted and inserted between two cities (breaking the third edge).

On the basis of this observation, 3-opt, as a heuristic, can be implemented as follows:

1. Let T be a current feasible solution;
2. Until $done = \text{TRUE}$,
 - a. For each city $i \in N$ and $j \in N \setminus \{i\}$: Consider inserting the inverted and uninverted set of cities between and including i and j with all other adjacent pairs of cities k and l in the tour. If the best exchange reduces the current tour length, reset T by making the insertion (and inversion, if required) in T ;
 - b. if no potential exchanges provide improvement, set $done = \text{TRUE}$.

The resulting tour is said to be 3-optimal.

Note that the edge insertion local search is a special case of the 3-opt, in which the edge to be moved in edge insertion is not inverted and therefore uniquely identifies the edges to be removed and reformed. Figure 4 shows how the tour ABCDEFGH can be transformed through an edge insertion or 3-opt move. First, consider how the

Figure 4. After an edge insertion OR 3-opt move.

result is achieved from the edge insertion point of view. The edge DE is removed from its original location between C and F and inserted between the nodes F and G, resulting in the tour ABCFDEGH. From the 3-opt point of view, we can see that this breaks three edges: CD, EF, and FG. The new edges are CF, FD, and EG.

Lin–Kernighan Heuristic. Laporte [6] reports that the dominant heuristics for symmetric TSPs are based on the Lin–Kernighan heuristic [15]. References [5] and [6] identify Helsgaun’s variant as performing very well, even for the asymmetric case [11]. The Lin–Kernighan Heuristic is much more complicated than any other method presented in this article. The basic idea is that the value of λ that should be used is unknown; the decision to use 2-opt or 3-opt, or a different value, is arbitrary. Therefore, begin by considering 2-opt and then incrementally consider increasing values of λ .

The Golden *et al.* [9] presentation of the Lin–Kernighan heuristic lies between the length in Refs 4 and 12. It is presented, slightly adapted, here for the convenience of the reader. G_p^* is the improvement that can be gained if the p edges currently under consideration are deleted and replaced with p different edges.

1. Let T be a current feasible solution.
2. Set $G_0^* = 0$. Select a city l and either edge including it from T , (l, k) for possible removal. Set $p = 1$.
3. Find the edge (k, i) not in T such that $i = \arg \max(g_1)$, where $g_1 = d_{lk} - d_{ki} > 0$. The value g_1 is positive when the selected edge is smaller than (l, k) ; we select the smallest of all such edges.
4. At this point, we anticipate that edge (l, k) will be removed and (k, i) will be added. Some edge currently incident to i must leave, or i will have degree 3. Select one of these edges, (i, j) , to leave. We could complete a 2-opt-type move at this time if we select the edge (j, l) to be added to T . If we did this (remove (l, k) and (i, j) , and add (k, i)

and (j, l) , $G_1^* = g_1 + d_{ij} - d_{jl}$. For now, assume that making this move will reduce the total tour length, meaning $G_1^* > 0$. If not, go to 2 and select a different city l .

5. However, it may be that edge (j, l) is not the one to be added. It may be that there is a different edge, adjacent to j , which would contribute more to reducing the tour length. To find the best of the edges adjacent with j , find the edge (j, m) not in T such that $m = \arg \max(g_p)$, where $g_1 = d_{ij} - d_{jm}$ (the edge (j, l) is one of the potential edges to be considered). Compute $G_p = \sum_{s=1}^p g_s$ and $G_p^* = G_p + c_{mn} - c_{nl}$. Let $G^* = \max_{s=1 \dots p} \{G_s^*\}$. Increment p and go to step 5 unless
 - No further feasible swaps exist.
 - the current configuration is a tour.
 - $G_p \leq 0$ (the attempt does not reduce the tour length).
 - $G_p \leq G^*$ (the attempt is worse than the best option seen so far).

Stop and select the best of the tours associated with the $G_s^*, s = 1 \dots p$ values.

The increased coding and computational complexity introduced by this algorithm, and particularly by Helsgaun's variant [16], appear to be justified by the quality of solutions found by it. Helsgaun finds several new upper bounds to symmetric problem instances in TSPLIB, as well as performing well for asymmetric instances.

CONCLUSION

This article has provided an overview of five construction heuristic classes and two improvement heuristic classes. While the literature contains endless variants of the TSP, these heuristic examples contain those that form the basis of understanding the TSP literature. The interested reader is directed to Refs 1–6 for more detailed comprehensive surveys of TSP heuristics, with extensive computational results, and to Ref. 7 for fast implementations of several methods.

Italy

ANDREA LODI
DEIS, Università di Bologna,
Bologna, Italy

INTRODUCTION

We consider a generic mixed integer linear program (MILP) in the form

$$\min c^T x \quad (1)$$

$$Ax \geq b \quad (2)$$

$$x_j \in \{0, 1\} \quad \forall j \in \mathcal{B}, \quad (3)$$

$$x_j \text{ integer} \quad \forall j \in \mathcal{G}, \quad (4)$$

$$x_j \text{ continuous}, \quad \forall j \in \mathcal{C}, \quad (5)$$

where A is an $m \times n$ input matrix, and b and c are input vectors of dimension m and n , respectively. Here, the variable index set $\mathcal{N} := \{1, \dots, n\}$ is partitioned into $(\mathcal{B}, \mathcal{G}, \mathcal{C})$, where $\mathcal{B}$ is the index set of the 0–1 variables (if any), while the sets $\mathcal{G}$ and $\mathcal{C}$ index the general integer and the continuous variables, respectively. Bound on the variables, including the 0–1 bounds on the binary ones, are assumed to be part of system (2). Removing the integrality requirement on variables indexed by $\mathcal{I} := \mathcal{B} \cup \mathcal{G}$ leads to the *LP relaxation* $\min\{c^T x : x \in P\}$ where $P := \{x \in \mathcal{R}^n : Ax \geq b\}$.

MILP heuristics aim at finding a feasible (and hopefully good) solution of the problem above, which is an NP-hard problem by itself. We next present the main ideas underlying some of the heuristics proposed in the literature. In this article, in particular, we focus on those algorithms developed with the aim of being tightly integrated within MILP solvers. We group and discuss the algorithms

depending on the main ingredient (building block) they use, namely LP-based heuristics in the section titled “LP-Based Heuristics” and MILP-based approaches in the section titled “MILP-Based Heuristics.”

With a little abuse of terminology, in what follows, we will say that a point x is *integer* if x_j is integer for all $j \in \mathcal{I}$ (no matter what the value of the other components), whereas the *rounding* $\tilde{x}$ of a given x will be defined as $\tilde{x}_j := \lfloor x_j \rfloor$ if $j \in \mathcal{I}$ and $\tilde{x}_j := x_j$ otherwise ($\lfloor \cdot \rfloor$ representing scalar rounding to the nearest integer).

We end the introduction by noting that, although Achterberg [1] has shown that the impact of heuristics is not dramatic in terms of ability of an MILP solver to prove optimality in a (much) quicker way, the psychological impact for the user who sees a high quality feasible solution provided very early is huge. For this reason, the availability of very effective general-purpose heuristics for MILP is among the most crucial improvements over the last 10 years.

LP-BASED HEURISTICS

In this section we address some basic heuristics that only assume the availability of a “black-box” LP solver.

Folklore

The so-called *rounding* as well as *diving* heuristics belong to folklore.

Rounding methods solve the LP relaxation to get an optimal point x^* , whose fractional components x_j^* with $j \in \mathcal{I}$ are rounded, for example, to their nearest integer value. Continuous variables, if any, can optimally be recomputed once the integer variables have been fixed by solving an LP.

Diving (also known as *Relax-and-Fix*) methods, instead, mimic an enumerative scheme by sequentially fixing some integer-valued variables that assume a fractional value in the solution of the current LP-relaxation. The sequence can be viewed

as “diving” on a branch-and-bound tree until a feasible (and hopefully good) MILP solution is found. A limited backtracking is often allowed to investigate alternative fixing patterns. Various variable-fixing (i.e., branching) policies have been used by different authors, all meant to hopefully reach deep branching nodes while maintaining a good LP relaxation lower bound value.

Pivoting Methods

These methods originate from the seminal work of Balas and Martin [2] in the late 1970s. The basic heuristic, called *Pivot and Complement* (P&C), applies to pure 0–1 integer linear programs (ILPs) with $\mathcal{G} = \mathcal{C} = \emptyset$. It is based on the observation that a feasible solution is just a basic solution of the LP relaxation where all 0–1 variables are non-basic (either at their lower or upper bound), that is, only the slack (continuous) variables on Equation (2) are allowed to be basic. Given an optimal basis of the LP relaxation, P&C then performs a systematic series of “non-standard” pivots in the attempt of driving as many 0–1 variables as possible out of the basis, while preserving primal feasibility and worsening the objective function as little as possible.

More specifically, the method prescribes the use of three types of pivots: (i) Type 1 pivots that maintain primal feasibility and increase the number of nonbasic 0–1 variables; (ii) Type 2 pivots that also maintain primal feasibility but leave the number of nonbasic 0–1 variables unchanged, while reducing the *infeasibility degree* of the current LP solution x^* , computed as $\sum_{j \in B} \min\{x_j^*, 1 - x_j^*\}$; (iii) Type 3 pivots that increase the number of nonbasic 0–1 variables at the price of producing a primal-infeasible point—a situation to be repaired at a later step of the procedure.

Nonbasic 0–1 variables can also be complemented with the aim of improving the solution quality or reducing its primal infeasibility, and reduced costs are exploited to fix variables when mathematically correct. The P&C heuristic was later improved by Løkketangen *et al.* [3] by adding tabu search to the basic mechanisms.

In the mid-1980s Balas and Martin [4] introduced a generalization of P&C to MILPs, called *pivot and shift*, where general integer variables are treated as 0–1 variables “centered” on the current LP solution, and some new types of “nonstandard” pivots are introduced. An elaboration with the same name of this idea was later proposed by Balas *et al.* [5]. Different extensions called *pivot*, *cut*, and *dive* and *pivot and Gomory cut* were proposed by Nediak and Eckstein [6] and by Gosh and Hayward [7], respectively.

OCTANE and Line Search Methods

Line search methods are based on the following construction. One starts from an LP relaxation optimal vertex x^* and draws a line toward a second point, for example, y , to be chosen according to a certain criterion. Thus, moving in a discretized way from x^* to y traces a discrete sequence of (say) K points $x^k := x^* + \alpha_k(y - x^*)$ for $0 = \alpha_1 < \dots < \alpha_K = 1$. Each x^k can therefore be associated (e.g., by rounding) with an integer point $\tilde{x}^k$ which is then checked for feasibility and possibly used to update a current-best MILP solution. Local shifts of the rounded variables are typically allowed in the attempt of improving the feasibility and/or quality of the rounded points.

Hillier [8] introduced this scheme by defining y so as to go inside P along a so-called *interior path*, the rational being supported by the geometrical intuition that (mainly for general integer MILPs) going inside P increases the chances the rounded point be feasible. A similar scheme was later adopted by Ibaraki *et al.* [9] and by Faaland and Hiller [10], where the sampling line segment $[x^*, y]$ is replaced by a sequence of linear segments $[x^*, y^1]$, $[y^1, y^2]$, $\dots$ approximating a curved search trajectory. Very recently, Naoum-Sawaya and Elhedhli [11] investigated the effect of replacing the LP solver by an analytic-center method.

OCTANE (for Octahedral Neighborhood Enumeration) is a line search method proposed by Balas *et al.* [12] for 0–1 ILPs. It also starts with an LP optimal vertex x^* and moves it along a certain search direction $y - x^*$. However, the integer (possibly infeasible) points discovered along this direction

are not defined through rounding, but exploit the following construction. Consider the center $x^0 = (1/2, \dots, 1/2)$ of the unit hypercube. For any vertex $\tilde{x}$ of the unit hypercube (not necessarily in P), define the hyperplane $H(\tilde{x})$ passing through $\tilde{x}$ and orthogonal to $\tilde{x} - x^0$.¹ Starting from x^* and going toward y one crosses, in sequence, certain hyperplanes $H(\tilde{x}^1), H(\tilde{x}^2), \dots$ whose generating 0–1 points $\tilde{x}^1, \tilde{x}^2, \dots$ are checked for feasibility and used to possibly update the current-best feasible solution. *OCTANE* prescribes to visit only a limited number of hyperplanes, and exploits an effective method for their enumeration.

Feasibility Pump

The *Feasibility Pump* (FP) is a method originally proposed by Fischetti *et al.* [13] for 0–1 MILPs ($\mathcal{G} = \emptyset$), and then extended by Bertacco *et al.* [14] to the general case. It is based on the observation that a feasible MILP solution is a point x of P that coincides with its rounding. Replacing “coincides” with “is as close as possible” leads to the following iterative scheme. FP works with a *pair* of points $(x^*, \tilde{x})$ with $x^* \in P$ and $\tilde{x}$ integer, that are iteratively updated with the aim of reducing as much as possible their L_1 -distance $\Delta(x^*, \tilde{x}) := \sum_{j \in \mathcal{I}} |x_j^* - \tilde{x}_j|$. In a sense, the method is aimed at “pumping” the integrality of $\tilde{x}$ into x^* , and the LP-feasibility of x^* into $\tilde{x}$ —hence its name.² To be more specific, one starts with any $x^* \in P$, for example, an optimal LP vertex, and initializes an integer $\tilde{x}$ as the rounding of x^* . At each FP iteration, called a *pumping cycle*, $\tilde{x}$ is fixed and one finds a point $x^* \in P$ which is as close as possible to $\tilde{x}$ by solving the auxiliary LP $\min\{\Delta(x, \tilde{x}) : x \in P\}$. If $\Delta(x^*, \tilde{x}) = 0$, then x^* is integer and the method is completed. Otherwise, $\tilde{x}$ is replaced by the rounding of x^* so as to hopefully reduce $\Delta(x^*, \tilde{x})$ even further, and the process is iterated. The basic

FP scheme above may stall in case $\Delta(x^*, \tilde{x})$ is not reduced at some iteration, hence a number of diversification mechanisms are introduced.

As stated, FP is meant to only produce a feasible MILP solution, as the objective function is only taken into account implicitly in the definition of the very first x^* . In order to produce good quality solutions, the original FP approach [13] uses a “sliding window” method that introduces the cut $c^T x \leq UB$ into the LP model and updates UB , on the fly, by taking an intermediate value between the optimal LP-relaxation and the UB values. (Note that the value UB can also be a “guess” of a feasible solution value and in such a case the cut can be possibly invalid.) A different approach, called *objective FP*, was developed by Achterberg and Berthold [15], who modified the objective function of the auxiliary LP to $\Delta(x^*, \tilde{x}) + \alpha c^T x$, where α is a dynamically updated parameter. Very recently, Fischetti and Salvagnin [16] proposed a more elaborated FP version, called FP 2.0, where the original rounding operation used to construct $\tilde{x}$ from x^* is replaced by a more clever rounding heuristic based on constraint propagation—a basic tool in constraint programming (see **Constraint Programming Links with Math Programming**).

MILP-BASED HEURISTICS

We next address a new generation of MILP heuristics that emerged in the late 1990s. Their hallmark is the use of a “black-box” external MILP solver to explore a solution neighborhood defined by invalid linear constraints. The use of an exact MILP solver inside an MILP heuristic may appear naive at first glance, but it turns out to be effective in the cases where the added invalid constraints lead to a structural simplification of the MILP at hand and allow, for example, for a more powerful instance preprocessing and/or for extensive node pruning.

Local Branching

The *local branching* (LB) scheme of Fischetti and Lodi [17] appears to be the first method

¹The half-spaces induced by these hyperplanes that contain x^0 define an octahedron, hence the name of the method.

²The name was actually inspired by the *Electron Pump* of the Asimov’s science fiction novel “The Gods Themselves”.

embedding an MILP solver within a general MILP heuristic framework. Suppose a feasible *reference solution* $\bar{x}$ of an MILP with $B \neq \emptyset$ is given, and one aims at finding an improved solution that is “not too far” from $\bar{x}$. To this end, one can define the *k-OPT neighborhood* $\mathcal{N}(\bar{x}, k)$ of $\bar{x}$ as the set of the MILP solutions satisfying the invalid *local branching constraint*

$$\Delta(x, \bar{x}) := \sum_{j \in B: \bar{x}_j = 0} x_j + \sum_{j \in B: \bar{x}_j = 1} (1 - x_j) \leq k, \quad (6)$$

for a small parameter k (typically, $k = 10$ or $k = 20$), and explore it by means of an external MILP solver, often heuristically, that is, within a prefixed number of branch-and-bound nodes. The method is in the spirit of local search metaheuristics and in particular of *large neighborhood search* [18], with the novelty that neighborhoods are obtained through a so-called *soft fixing*, that is, through invalid cuts to be added to the original MILP model. Diversification cuts can be defined in a similar way, thus leading to a flexible toolkit for the definition of metaheuristics for general MILPs. For example, Hansen *et al.* [19] embedded LB within variable neighborhood search, whereas Fischetti *et al.* [20] specialized LB to MILPs with a two-level variable structure. Integration between FP and LB was instead proposed by Fischetti and Lodi [21].

As its name suggests, LB can also be used within an exact enumerative scheme by branching on the “local” disjunction $\Delta(x, \bar{x}) \leq k$ (to be explored first) or $\Delta(x, \bar{x}) \geq k + 1$ with respect to the incumbent MILP solution $\bar{x}$ (no matter the LP solution at a given node). This branching strategy is intended to favor the detection of good solutions very early in the enumeration.

Relaxation Induced Neighborhood Search and Variants

The *relaxation induced neighborhood search* (RINS) framework of Danna *et al.* [22] also uses the (heuristic) solution of a simplified MILP through an external MILP solver as a main ingredient, but extends the idea by taking the solution of the LP relaxations into

account. At specified nodes of the branch-and-bound tree, the current LP relaxation solution x^* and the incumbent $\bar{x}$ are compared and all integer-constrained variables that agree in value are fixed and projected out of the MILP. In this way, such an MILP is not only simplified but generally speaking (provided the number of components fixed is sufficiently large) it is also reduced in size. This is probably the main difference between LB and RINS, namely the fact that the former performs a *soft* fixing by means of the cardinality constraint (6), while in the latter the fixing is *hard* with clear benefits associated with dealing with smaller MILPs.

The RINS framework is also particularly suitable for an integration within a classical branch-and-bound (and then within classical MILP solvers) because it can be virtually invoked at any node of the tree where solutions of the LP relaxations are always different. Clearly, invoking the algorithm too often would result in slowing down the overall running time for proving optimality, thus RINS is only executed every L (say) nodes in the tree. On the other hand, the size of the resulting *reduced* MILP cannot be predicted in advance and the MILP is solved only if the reduction is relevant enough.

The *distance* induced neighborhood search (DINS) approach by Ghosh [23] is a RINS variant which takes an intermediate step between LB and RINS by performing both soft and hard fixing within the same algorithm. The idea behind DINS is that the most promising solutions are those “close” to the solution of the continuous relaxation, thus the neighborhood is defined by the distance inequality

$$\sum_{j \in B \cup G} |x_j - x_j^*| \leq \sum_{j \in B \cup G} |\bar{x}_j - x_j^*|, \quad (7)$$

where again x^* and $\bar{x}$ denote the current LP solution of the LP relaxation and the incumbent, respectively. For a variable x_j such that $|\bar{x}_j - x_j^*| < 0.5$ the only way for the new solution to decrease its distance with respect to $\bar{x}_j$ is to hard fix it, that is, $x_j = \bar{x}_j$. For the other variables, instead, a *rebounding* phase is performed before the neighborhood is explored (as usual by means of a call to an

external MILP solver), in which the bounds on the variables are set so as the absolute value of the distance between the new solution and $\bar{x}$ cannot increase. A bit more of flexibility can be granted by allowing some of the variables to increase their distance but reducing the overall distance (as guaranteed by Equation 7). This is again obtained by a sophisticated mixture of hard and soft fixing.

The relaxation *enforced* neighborhood search (RENS) scheme by Berthold [24] is another RINS approach whose main characteristic is to define a reduced MILP (to be explored by a call to an external solver) as the set of all integer solutions which can be obtained by rounding a solution $x^* \in P$. More precisely, for a given x^* the reduced MILP is constructed by

1. *hard fixing* those integer-constrained variables whose current value is already integer, that is, $x_j = x_j^*, \forall j \in F$ where $F := \{j : x_j^* = \lfloor x_j^* \rfloor, j \in \mathcal{B} \cup \mathcal{G}\}$;
2. *rebounding* the remaining variables by using the two rounded values as lower ℓ_j and upper u_j bounds, that is, $\ell_j = \lfloor x_j^* \rfloor$ and $u_j = \lceil x_j^* \rceil$ for all $j \in (\mathcal{B} \cup \mathcal{G}) \setminus F$.

Interestingly, RENS does not require an incumbent solution to work with and it can be used offline as a tool for the analysis of the effectiveness of MILP rounding heuristics. Note that pivot-and-shift [5] uses a similar mechanism to restrict the range of the integer variables depending on their LP value and such a rebounding is similar to that of DINS as well.

An Evolutionary Algorithm within MILP

The farthest (to date) step in the direction of using metaheuristic ideas within an MILP has been taken by Rothberg [25]. The resulting approach, often called *polishing* algorithm, implements an evolutionary heuristic which is invoked at selected nodes of a branch-and-bound tree and includes all classical ingredients of genetic computation. More precisely,

- *Population*. A fixed-size population of feasible solutions is maintained. Those

solutions are either obtained within the tree (by other heuristics, including diving) or computed by the polishing algorithm itself.

- *Combination*. Two or more solutions (the parents) are combined with the aim of creating a new member of the population (the child) with “improved” characteristics. The RINS scheme is adopted, that is, all variables whose value coincides in the parents are fixed and the reduced MILP is heuristically solved by an external MILP solver within a limited number of branch-and-bound nodes. This scheme, clearly, is much more time-consuming than a classical combination step in evolutionary algorithms, but guarantees that the child solution is feasible (for the original problem).
- *Mutation*. A sufficient degree of diversification is guaranteed by performing a classical mutation action which consists in (i) selecting at random a *seed* solution in the population, (ii) fixing at random some of its variables, and (iii) heuristically solve the resulting reduced MILP.
- *Selection*. The parents’ selection is performed in a simple way by randomly picking a solution in the population and then choosing, again at random, the second one but only among those solutions with a better objective value. Although it is easy to extend this criterion to select more than two parents, in Rothberg [25] either two or all solutions are used as parents, that is, in the latter case no selection is performed.

The polishing algorithm is then a fully general metaheuristic implemented within an MILP framework and, in turn, making use of an external MILP solver as main “engine.”

Constraint programming (CP) is a technology for solving combinatorial optimization problems in areas such as scheduling, configuration, vehicle routing, networking, and bioinformatics. It can be seen as a field on the edge between “mathematical programming” and “computer programming.” In “mathematical programming,” the users declaratively specify the problem to be solved, and the underlying solution mechanism generates a solution. In “computer programming,” the users—the programmers—have to explicitly instruct the computer how to produce the solution. In CP also, the users declaratively specify the problems—this is called *constraint modeling* and the problems are formulated as constraint satisfaction problems (CSP), but the users can also help the solution mechanism, for example, by programming a specific strategy to search for a solution. Constraint modeling is more flexible and closer to formal problem specification than, for example, the problem formulation in mathematical programming. Hence, CP is sometimes seen as *one of the closest approaches computer science has yet made to the Holy Grail of programming: the user states the problem; the computer solves it* [1].

The formulation of a CSP is extremely simple—the problem consists of a finite set X of variables, each variable $x_i \in X$ has assigned a set D_i of possible values that can be used for instantiation of x_i —its domain—and finally there is a finite set of constraints that restrict possible combinations of values assigned to the variables. The constraint on a set of variables can

be expressed in extension as a set of value tuples that can be consistently assigned to these variables or used as an arithmetical or a logical formula. More formally, the constraint is any relation over the set of variables—it is defined as a subset of the Cartesian product of domains of the constrained variables. A solution to a CSP is a complete instantiation of variables satisfying all constraints. A nice example of a CSP is the well-known Sudoku puzzle, where the variables correspond to the cells, each domain consists of numbers 1 to 9, and there is a constraint forcing inequality between any pair of variables corresponding to the cells in the same row, in the same column, and in the same subgrid. Another well-known example is the graph-coloring problem, that can be directly encoded as a CSP (the nodes specify the variables; the colors are possible values for the variables, and the arcs define binary constraints forcing inequality).

There are two important special classes of CSPs: Boolean CSPs, where the domains contain only 0 and 1 and the constraints describe logical relations, and binary CSPs, where all constraints are binary relations. While Boolean CSPs naturally model satisfiability problems and hence show that CSPs, in general, are NP-complete problems (though there are tractable classes as described further), binary CSPs were the topic of initial studies in the area of constraint satisfaction, and many constraint satisfaction algorithms were initially formulated and studied for binary constraints. There also exist extensions of classical CSPs, for example, soft CSPs and constraint optimization problems (COP). In soft CSPs, some constraints can be relaxed and the task is to satisfy as many constraints as possible (other formulations also exist [2]), while in a COP a given objective function evaluates the solutions of the underlying CSP and the task is to minimize or maximize the value of such a function.

The solving technology behind CP originates mostly in artificial intelligence, but nowadays it also absorbs techniques from

fields such as databases, discrete mathematics, numerical mathematics, and operations research. This article gives a brief overview of how constraint satisfaction technology evolved. We focus mainly on constraint satisfaction over discrete finite domains, which forms the vast majority of research in the area of constraint satisfaction. There are also studies of usually more complex problems over real numbers and other domains.

THE ANCIENT TIMES

Though frequently (and wrongly) CP is used as a synonym for enumeration or search, the truth is that a specific form of inference called *constraint propagation* is much more typical to CP. Nevertheless, taking search as one of the core technologies behind CP, we can trace the roots of CP as back as to ancient Greeks, namely to the myth on Theseus who used backtrack-like search to escape from the Crete's Labyrinth inhabited by a Minotaur [3]. Backtrack search was used in the nineteenth century to solve problems in recreational mathematics [4], and it was an early subject of study in fields such as operations research. The backtracking algorithm was informally described by Golomb and Baumert [5], but a nonrecursive formulation of Bitner and Reingold [6] is used more frequently.

As mentioned above, inference techniques are more typical to CP. Again, going to ancient Greeks, Diophantine equations named after the Greek mathematician Diophantus can be seen as a special form of a CSP [7]. These equational constraints with integer domains were solved by the Indian mathematician Brahmagupta in the seventh century [8]. Probably more known works in this area are results by Gauss, who studied systematic methods for solving linear equations by variable elimination [9], and the works by Fourier who solved linear inequality constraints [10]. The ideas of Gauss and Fourier are reflected in some modern approaches of constraint solving [11].

THE BEGINNING

Artificial intelligence has its birth year in 1956, when this name for a new research

field was proposed by McCarthy at the Dartmouth workshop [12]. The birth year of CP can be set in 1963, when Ivan Sutherland in his MIT PhD Thesis described the system Sketchpad—an interactive graphics application that allowed the user to draw and manipulate constrained geometric figures on computer display [13]. This ancestor of modern drawing programs and CAD tools had a follower in the system ThingLab by Alan Borning [14], where preferential constraints can be precompiled to resatisfy them quickly after changing values of some variables representing positions of a computer mouse. Yes, the computer mouse existed before Apple Macintosh appeared in 1984. The common idea of these systems is that rather than writing ad hoc procedures for the manipulation of graphical objects, the user declares the constraints about these objects and the system automatically maintains these constraints while the user manipulates any object. Since Sketchpad in 1963, two parallel streams of CP developed, that Freuder and Mackworth [15] call the “language” stream and the “algorithm” stream.

The language stream represents the effort on developing novel programming languages and systems motivated by applications in various domains. For example, the research in the field of electric circuit analysis and design at MIT led to the language CONSTRAINTS [16]. Fikes [17] described REF-ARF, which was a part of a general problem-solving system that employed constraint satisfaction as one of its parts. Another notable language was Alice by Lauriere [18]. This purely declarative language used high level objects such as functions and relations to model combinatorial problems. Constraint solving was handled by consistency methods as well as by reasoning about abstract functions. Other systems and languages that include some form of constraint reasoning and that were developed in this period are Absys—a declarative language based on manipulation of equational constraints [19], MOLGEN—an expert system for problems in the area of molecular genetics [20], and PLANNER—a language for proving theorems in robots [21]. From the current perspective, the real landmark in the

area of languages for constraint satisfaction was the development of the programming language Prolog by Alain Colmerauer and Philippe Roussel [22]. Prolog (programmation en logique—French for programming in logic) is a logic programming language that was originally developed for the area of computation linguistics, and is based on Robert Kowalski's procedural interpretation of Horn clauses [23]. Prolog can be seen as an early CP language, where the equality constraints over the terms are solved by the unification algorithm. Colmerauer further developed this idea in Prolog II that supported equations and inequalities over the rational trees [24]. Prolog II can be seen as the first logic programming language that explicitly used constraints. The successor—Prolog III—is a real constraint logic programming language providing the constraints over the Booleans, linear arithmetic over the rational numbers, and the constraints over the lists [25]. It was used in several application areas such as chemical reasoning, diagnosis problems, and scheduling problems.

The algorithm stream was another constraint-related stream in artificial intelligence in the 1970s. It was motivated by the research in the area of machine vision, and the first landmark was the development of filtering algorithms for scene labeling by David Waltz [26]. Scene labeling was one of the first problems formulated as a CSP—the lines in the scene define the variables, each line is to be annotated either as convex, concave or boundary (these are the values in the domain), and the junctions of the lines define the constraints describing physically feasible combinations of edge types. Waltz suggested an algorithm for pruning the infeasible values, which is called *domain filtering*. This constraint propagation (arc consistency) algorithm is today known as AC-2, and it started the research in the area of constraint consistency techniques. Ugo Montanari proposed the notion of path consistency and established the general framework for reasoning with constraints [27]. The notions of arc and path consistency are derived from the graph representation of a binary CSP, where the nodes describe the variables and the arcs describe the

binary constraints. In arc consistency, we require that each value in the domain of a variable has a compatible value (support) in the domain of a connected variable, where compatibility means that the pair of values satisfies all constraints between these two variables. In path consistency, we require that two values from the domains of two variables have a common support in the domain of any third variable. Alan Mackworth described the basic arc and path consistency algorithms AC-1, AC-2, AC-3, PC-1, and PC-2 [28] and together with Eugene Freuder studied their complexity [29]. The idea of AC-3 is still in the core of many current constraint solvers. Mackworth also extended the definitions and the consistency algorithms to nonbinary constraints [30], while Freuder generalized arc and path consistency to k -consistency [31] and later to (i, j) consistency [32]. In k -consistency, we require that any consistent instantiation of $k - 1$ different variables can be consistently extended to any additional variable, while (i, j) -consistency generalizes this idea by requiring any consistent instantiation of i different variables to be consistently extendable to any additional j variables.

THE REAL START

The research in the 1970s prepared a base for expansion of constraint satisfaction techniques and for joining the language and the algorithm streams. As already mentioned, the development of Prolog was one of the landmarks in the area of constraint satisfaction. Researchers realized that unification in Prolog is just a special form of constraint reasoning, and this observation started the systematic use of constraints in programming. Constraint logic programming (CLP) was born [33]. There were three independent research teams working on concepts of CLP. We already mentioned Alain Colmerauer and his Prolog II and Prolog III systems. The actual notion of CLP was proposed by Jaffar and Lassez in 1986 [33]. They gave a general schema and semantics for the class of CLP languages, and they developed the language CLP(R) which was an extension of Prolog with the arithmetic constraints over the real

numbers [34]. They used an incremental simplex algorithm for solving the linear constraints, while the evaluation of the nonlinear constraints was delayed until they became linear or sufficiently ground. This system was used in financial modeling and in several engineering applications. The real join of the algorithm and the language streams can, however, be seen in the third system. The team led by Mehmet Dincbas with notable contributions from Pascal Van Hentenryck, Helmut Simonis, and others in the European Computer-Industry Research Center (ECRC) developed the system CHIP (constraint handling in Prolog) [35]. This system solved the combinatorial problems, and it combined Prolog's backtracking search with the consistency techniques. It was the first CLP language focusing on constraint satisfaction over the finite domains. The main application areas were scheduling, circuit diagnosis, and cutting stock problems. The architecture of CHIP, the combination of its backtracking search and consistency techniques, can be seen as the mainstream constraint satisfaction approach. Many later systems employed the same schema. The first book on CP [35], which described the principles of CHIP, was published at that time.

DEVELOPING THE CORE CONCEPTS

When the base solving approach for CP, the combination of its search techniques with inference techniques based on constraint propagation, was established, the research focused on both these areas independently as well as on their efficient integration.

The research on search techniques followed the work on backtracking search by providing several improvements. One branch focused on improving the inefficiencies of chronological backtracking when going back during search. *Backjumping* was introduced by Gaschnig [36] to recover from a known problem of backtracking called *thrashing* (when going back, the search algorithm does not exploit information about the reason of the failure). On the other hand, backjumping can jump to the variable causing the conflict during the search rather than trying different instantiations of the variables that are

not related to the conflict. A graph-based variant of backjumping that exploits the structure of the constraint graph and, hence, can jump back several times was proposed by Dechter [37]. Prosser then combined both ideas and suggested conflict-directed backjumping [38]. One of the disadvantages of backjumping is that it forgets the assignment of variables that are jumped across. *Dynamic backtracking* proposed by Ginsberg [39] solves this problem by dynamic variable reordering during search. Another approach for improving chronological backtracking was based on remembering the result of constraint checks, so the next time the same check is done, the result can be retrieved and used. This technique for removing redundant constraint checks called *backmarking* was proposed by Haralick and Elliot [40]. Together with other techniques that, for example, record no-goods discovered during search, these improvements of chronological backtracking are known under the umbrella term *intelligent backtracking* or *look-back* search techniques.

Other efforts focused on exploiting heuristics during search. When instantiating a variable, there are basically two types of heuristics necessary to guide the search: the variable ordering heuristics to select the variable for instantiation, and the value ordering heuristics to select the value to be assigned to the variable. Already Golomb and Baumert proposed variable ordering heuristic, suggesting to instantiate first the variable with the smallest domain [5]. This is called the *dom heuristic* today. Haralick and Elliot [40] later generalized this principle and give it a name—a *fail-first principle* (select the variable whose instantiation will lead to a failure with the highest chance). Motivated by the graph-coloring problems, Brélaz [41] suggested combining the dom heuristic with information about the number of constraints in which the variable participates (the variables participating in more constraints are tried first). This is called the *dom+deg heuristic* (select the variable with the smallest domain and break ties by preferring the variable participating in more constraints). Another variation of this heuristic called *dom/deg* was suggested by

Bessiere and Regin [42]. All these heuristics try to exploit the graphical structure of a CSP. There is also an “independent” research branch studying how the structure of CSPs can be exploited during problem solving. Already Freuder [43] showed that ordering the variables based on the width of the constraint graph can lead to solving the problem without any backtrack. The variable ordering giving the smallest width of the constraint graph is used, where the width is the maximal number of backward edges in the ordered graph. In particular, Freuder proved that if the problem is k -consistent for any k between 1 and $w + 1$, where w is the width of the graph, then the above ordering leads to backtrack-free search. Dechter and Pearl [44] suggested another structure-based heuristic that instantiates first the variables that cut cycles in the constraint graph. The motivation is hidden in the observation that tree-structured CSPs can be solved in polynomial time [43], and this heuristic tries to reduce the problem into a tree-structured one. These structure-based heuristics are not frequently used today because they can break down in the presence of global constraints.

While the generally applicable variable ordering heuristics are widely used, the value ordering heuristics are more frequently problem dependent. The values are selected based on their meaning in the problem. Nevertheless, the problem-independent value ordering heuristics were also proposed and studied. Dechter and Pearl [44] suggested approximating the number of solutions by solving a tree relaxation of the problem and preferring the values that lead to more solutions in such tree relaxations. An easier way is to assign the value to the variable, propagate this instantiation to other variables through the constraints (e.g., by making the problem arc consistent), and then to select the variable based on the size of the resulting domains. Ginsberg *et al.* [45] proposed to select first the value that maximizes the product of the remaining domain sizes—a so-called *promise heuristic*. Frost and Dechter [46] suggested selecting first the value that maximizes the sum of the remaining domain sizes—a so-called *min-conflict heuristic*.

While the heuristics drive the search algorithm toward the solution, they cannot guarantee to be always correct, that is, to lead to the solution without any backtrack. Hence a research branch studying how to recover from the failure of the heuristics appeared. It was pioneered by Harvey and Ginsberg [47], who developed a so-called *limited discrepancy search* motivated by two features of good value ordering heuristics. First, the number of times the heuristic is wrong—a so-called discrepancy—is usually small. Second, if there are any discrepancies, then they appear earlier in the search tree. Other discrepancy-based search techniques were proposed later; for example, an improved limited discrepancy search by Korf [48], the discrepancy-bounded depth-first search by Beck and Perron [49], the interleaved depth-first search by Meseguer [50], and the depth-bounded discrepancy search by Walsh [51].

Another research branch focused on consistency techniques. The original arc and path consistency algorithms proposed in Mackworth [28] were not optimal regarding the time efficiency. Mohr and Henderson [52] proposed an optimal worst-case time complexity algorithm AC-4 to achieve arc consistency. This algorithm was based on the idea of keeping all supports for each value and removing that value from the domain when it lost all supports. The main disadvantage of this algorithm was large memory consumption (to remember all supports) and also the feature that the average time complexity was close to the worst case, so the nonoptimal AC-3 was better in average. Hence, Bessiere [53] proposed an improvement called AC-6 based on the idea that it is enough to keep a single support for each value and when the support is lost, the algorithm tries to find another one (if not possible, then the value is removed from the domain). Further improvement led to AC-7 [54] that exploits bidirectionality of constraints; that is, each value is a support for its own support. While AC-6 and AC-7 are based on the original idea of AC-4, the optimal versions of AC-3 algorithm were also proposed at an IJCAI 2001 conference. Zhang and Yap proposed

the algorithm AC-3.1 [55], and Bessiere and Regin proposed the algorithm AC-2001 [56]. Both algorithms combined the idea of AC-6 with the structure of AC-3. In the above listing of AC algorithms, we intentionally skipped algorithm AC-5 [57], which was going in a different direction. AC-5 is a general schema for AC algorithms, and depending on which subroutines are used, it can coincide with AC-3, AC-4, or other concrete algorithm for arc consistency. Moreover, this schema covers special filtering techniques for functional ($=$), antifunctional ($\neq$), and monotonic ($<$) constraints showing that the semantics of the constraint can be exploited during domain filtering. The concept of global constraints that heavily exploit the semantics of the constraint during domain filtering is discussed later.

Today, arc consistency is the most prominent inference technique in CP, but other consistency techniques were also studied. As mentioned, the notion of path consistency was introduced by Montanari [27], and Mackworth proposed the first path consistency algorithms PC-1 and PC-2 [28]. Mohr and Henderson [52] tried to develop a more efficient version of the path consistency algorithm using the same idea as in AC-4. This algorithm, called PC-3, is not sound as it may filter out a value that is consistent. Two years later, Han and Lee corrected this algorithm and called the new algorithm PC-4 [58]. The research of path consistency algorithms closely followed the novel ideas developed for the arc consistency algorithms, and Singh proposed the algorithm PC-5 [59] exploiting the idea of AC-6. At the same time, Berlandier also proposed a novel consistency level between arc and path consistency [60]. He called it *restricted path consistency* and the algorithm integrated some ideas of path consistency into the AC-4 algorithm. For a small overhead, this algorithm can remove more inconsistent values than arc consistency without the deficiencies of path consistency such as large memory consumption and changing the structure of the constraint graph. Other consistency levels were also studied, namely inverse consistency [61], which is basically (i, j) -consistency, where $i = 1$; neighbourhood

inverse consistency [62], where a value of a variable is required to be consistently extendable to neighbourhood variables; and singleton consistency [63] that can strengthen other consistency levels. For example, singleton arc consistency requires that the problem can be made arc consistent after instantiating any variable.

The early research on constraint satisfaction focused on binary CSPs and many of the above described results were formulated for binary constraints. Nevertheless, the constraints in practical applications frequently have an arity greater than two. Fortunately, n -ary constraints can be converted to the equivalent set of binary constraints. It was Montanari, who suggested the first conversion of an n -ary constraint to a set of binary constraints by projection [27]. However, the obtained set of binary constraints is not equivalent to the original n -ary constraint (some value tuples forbidden by the n -ary constraint may be allowed by the set of binary constraints). The equivalent encodings of n -ary constraints as binary CSPs were proposed and studied by Bacchus and van Beek [64] and Rossi *et al.* [65]. From the other perspective, Mackworth extended the definitions and the consistency algorithms to nonbinary constraints [30], which opened the area for constraint satisfaction algorithms for n -ary constraints. It is possible to directly extend the concept of arc consistency to n -ary constraints, which is called *generalized arc consistency*, or sometimes hyper arc consistency or domain consistency. The critical point for the efficiency of these algorithms is how to realize domain filtering for n -ary constraints. One can generalize the techniques from the binary constraints, but it is usually more efficient to exploit the semantics of the constraint as first suggested in AC-5 [57]. This is when the so-called global constraints were born. A *global constraint* is an n -ary constraint, where the arity is not fixed (the filtering algorithm can work with any arity). Probably the most well-known example of global constraint is *all-different* that encapsulates a set of binary inequality constraints. An efficient filtering algorithm for this constraint was proposed by Régin [66]. Since that time, many other

global constraints, frequently motivated by some application, have been proposed. Régim [67] generalized the all-different constraint into the *global cardinality constraint* (each value appears a given number of times in the set of variables). Pesant proposed the *regular constraint* (the sequence of values assigned to variables forms a word that is accepted by a finite automaton) [68], but the idea of a filtering algorithm was already presented by Barták [69]. The *grammar constraint* uses the same motivation, but the sequence of values is given by a grammar rather than by an automaton [70]. It was the CP system CHIP (a follower of the original CHIP from ECRC) marketed by Cosytec that popularized the idea of global constraints. Beldiceanu *et al.* attempted to classify the global constraints using the formalism of graph invariants [71].

So far we have discussed two separate streams of research that we can call the search stream and the consistency (or inference) stream. Both of them are integrated in a typical CP system. We already mentioned the look-back schemes, where the constraints are used mainly to check whether or not the partial instantiation of the variables satisfies the constraints. The inference techniques can instead be used over the not-yet instantiated variables to detect a possible future failure of the search algorithm. This is called a *look ahead scheme*. The simplest way is propagating information about the currently instantiated variable to its direct neighbors. This is called *forward checking* and it was proposed by McGregor for binary constraints [72], and extended to the n -ary constraints by van Hentenryck [35]. One can propagate the instantiation further to even more distant variables but still in the direction from the currently instantiated variable to the not-yet instantiated variables. This is called *partial look ahead*, and it was proposed by Haralick and Elliot [40]. Even before, Gaschnig suggested maintaining arc consistency during search. That is, after instantiating the variable, the problem is made arc consistent and, if this is not possible, then backtracking is forced. He called this technique *full look ahead* [73]. The very same idea was explored under the name *maintaining arc consistency* (MAC) in Sabin and Freuder [74]. For a

long time, researchers were convinced that partial look ahead was more efficient than full look ahead, which pruned more of the search space but also added more overhead. It was Sabin and Freuder [74] who showed that for the difficult problems MAC solves the problems much faster than partial look ahead. The MAC algorithm forms the most frequently used solution approach in modern CP systems. The recent trend in integration of search and inference goes toward randomized versions of backtracking search with random restarts, where the information from one search iteration can be exploited during the inference in subsequent iterations [75].

COMMUNITY ASPECTS

So far we focused on the research aspects in the history of CP, but it is also interesting to see how the community evolved. At the beginning, there were only a few people developing this new solution technology, mainly under the umbrella of artificial intelligence. We gave names of some of them in the above paragraphs. It was in 1993 when the first workshop on Principles and Practice of Constraint Programming was organized at Newport, Rhode Island, United States. After the second workshop in 1994, the workshop changed to a conference with formal proceedings published in the Springer LNCS series. The first international conference on Principles and Practice of Constraint Programming was organized in 1995, in Cassis, France. This year can be seen as the year when the CP community was formally born. This started the series of annual conferences known under the acronym CP that is a prominent forum, where researchers working in the area of CP meet and discuss novel developments. At the end of the twentieth century, there was a series of sister conferences on practical applications of CP called PACT (The Practical Application of Constraint Technology), but it disappeared after a few editions. As the scope of CP was broadening and the originally AI-based technology started to absorb results from other research areas, namely operations research, another CP-related conference appeared. After a series of successful

workshops, in 2004, the first international conference on Integration of AI and OR Techniques in Constraint Programming (CP-AI-OR) was held in Nice, France. Since that time, the CP-AI-OR conference is organized annually and complements the CP conference by focusing on integration of techniques from different fields. In addition to these two major CP-related conferences, there is a special publication forum for researchers in the area of CP. In 1996, the Constraints journal (Kluwer) was started with Eugene Freuder as the first Editor-In-Chief. This journal “provides a common forum for the many disciplines involved in CP, constraint satisfaction, and optimization, and the many application domains in which constraint technology is employed” [76].

The CP community is now governed by the Association for Constraint Programming. This nonprofit international organization was formally established in 2005, and it undertook the role of the Constraint Programming Organizing Committee that started with the first CP conference in 1995 and coordinated the activities around the CP conference. “The Association for Constraint Programming aims at promoting CP in every aspect of the scientific world, by encouraging its theoretical and practical developments, its teaching in the academic institutions, its adoption in the industrial world, and its use in the application fields” [77]. In addition to taking care of the CP conferences, the association supports other CP-related activities such as summer schools.

The evolution of CP can also be nicely observed in published books. We already mentioned the pioneering book *Constraint Satisfaction in Logic Programming* by Pascal Van Hentenryck published in 1989 [35]. The book shows how the CP started, and the ideas from this book are still used in modern CP systems. The first book that can be assumed as a textbook on CP is *Foundations of Constraint Satisfaction* by Edward Tsang published in 1993 [78]. Prior to this book, the material on constraint satisfaction was scattered and the lack of organization made it hard to study. *Foundations of Constraint Satisfaction* consolidated

the material in the way that is appropriate for teaching and study of this area. In 1998, a new book following the style of *Constraint Satisfaction of Logic Programming* was published—*Programming with Constraints: An Introduction* by Marriott and Stuckey [79]. This book is targeted at practitioners of constraint satisfaction technology. The reader is guided using examples through problem modeling, using appropriate data structures, and controlling search. The book represents the language stream of research. In 2003, three new books on CP were published. The book *Essentials of Constraint Programming* by Abdennadher and Frühwirth [80] presents constraint handling rules as the universal language for writing constraint solvers. The book *Principles of Constraint Programming* by Apt [81] brings a novel unifying view of CP, where the constraint solvers and local consistency are presented by means of rules and the constraint propagation algorithms by means of the generic iteration algorithms. Finally, the book *Constraint Processing* by Dechter [82] is a good textbook covering basics of constraint processing as well as advanced constraint satisfaction methods. Among the other books on CP published later, *The Handbook of Constraint Programming* [83] must be mentioned as it provides a comprehensive survey of the area of CP written in the encyclopedic style. It was also a valuable source of information for this article.

MATHEMATICAL MODELING, ALGEBRA, SYSTEMS OF LINEAR EQUATIONS, AND LINEAR ALGEBRA

One of the most fundamental ideas of the human mind, discovered more than 5000 years ago by the Chinese, Indians, Iranians, and Babylonians, is to represent quantities that we want to determine by symbols—usually letters of the alphabet like x, y, z —then express the relationships between the quantities represented by these symbols in the form of equations, and finally, use these equations as tools to find out the true values represented by the symbols. The symbols representing the unknown quantities to be determined are now called *unknowns*, *variables*, or *decision variables*.

The process of representing the relationships between the variables through equations or other functional relationships is called *modeling* or *mathematical modeling*. The earliest mathematical models constructed were *systems of linear equations*, and soon after, the famous *elimination method* for solving them was discovered in China and India.

The Chinese text *Chiu-Chang Suanshu* (*Nine Chapters on the Mathematical Art*) compiled over 2000 years ago describes the method using a problem of determining the yield (measured in units called *tou*) from three types of grain—inferior, medium, superior—given the yield data from three experiments, each using a separate combination of the three types of grain. See

Kangshen *et al.* [1] for information on this ancient work, also a summary of this ancient Chinese text can be seen at the following website: http://www-groups.dcs.st-and.ac.uk/~history/HistTopics/Nine_chapters.html.

Ancient Indian texts *Sulva Suutrah* (*Procedures Based on Ropes*), and the *Bakhshali Manuscript*, which date back to the same period, describe the method in terms of solving systems of two (three) linear equations in two (three) variables; see Refs 2 and 3 for information on these texts. For a summary and review of this book see <http://www.tlca.com/adults/origin-math.html>.

This effort culminated around 825 AD in the writing of two books by the Persian mathematician Muhammad ibn-Musa Alkhawarizmi in Arabic; this attracted international attention. The first was *Al-Maqala fi Hisab al-jabr w'almuqabilah* (*An essay on algebra and equations*). The term *al-jabr* in Arabic means “restoring” in the sense of solving an equation. In Latin translation, the title of this book became *Ludus Algebrae*, the second word in this title surviving as the modern word *algebra* for the subject, and Alkhawarizmi is regarded as the father of algebra. *Linear algebra* is the name subsequently given to the branch of algebra dealing with systems of linear equations. The word *linear* in “linear algebra” refers to the *linear combinations* in the spaces studied, and the *linearity* of “linear functions” and “linear equations” studied in the subject.

The second book, *Kitab al-Jam'a wal-Tafreeq bil Hisab al-Hindi*, appeared in a Latin translation under the title *Algoritmi de Numero Indorum*, meaning *Al-Khwarizmi Concerning the Hindu Art of Reckoning*; it was based on earlier Indian and Arabic treatises. This book survives only in its Latin translation, because all copies of the original Arabic version have been lost or destroyed. The word *algorithm* (meaning procedures for solving algebraic systems) originated from the title of this Latin translation. Algo-

rithms seem to have originated in the work of ancient Indian mathematicians on rules for solving linear and quadratic equations.

An Example Application

Here is an example application from Murty [4] that leads to a model involving simultaneous linear equations. A steel company has four different types of scrap metal (called *SM-1* to *SM-4*) with compositions as given in Table 1. They need to blend these four scrap metals into a mixture for which the composition by weight is Al, 4.43%; Si, 3.22%; C, 3.89%; Fe, 88.46%. How should they prepare this mixture?

To answer this question, we first define the decision variables, denoted by x_1, x_2, x_3, x_4 , where for $j = 1$ to 4 , x_j = proportion of *SM-j* by weight in the mixture to be prepared. Then the percentage by weight of the element Al in the mixture will be $5x_1 + 7x_2 + 2x_3 + x_4$, which is required to be 4.43. Arguing the same way for the percentage by weight in the mixture of the elements Si, C, and Fe, we find that the decision variables x_1 to x_4 must satisfy each equation in the following system of linear equations in order to lead to the desired mixture:

$$\begin{aligned} 5x_1 + 7x_2 + 2x_3 + x_4 &= 4.43, \\ 3x_1 + 6x_2 + x_3 + 2x_4 &= 3.22, \\ 4x_1 + 5x_2 + 3x_3 + x_4 &= 3.89, \\ 88x_1 + 82x_2 + 94x_3 + 96x_4 &= 88.46, \\ x_1 + x_2 + x_3 + x_4 &= 1. \end{aligned}$$

The last equation in the system stems from the fact that the sum of the proportions of various ingredients in a blend must always be equal to 1. From the definition of

Table 1. Compositions of Available Scrap Metals

Type	% in type, by weight, of element			
	Al	Si	C	Fe
SM-1	5	3	4	88
SM-2	7	6	5	82
SM-3	2	1	3	94
SM-4	1	2	1	96

the variables given above, it is clear that a solution to this system of equations makes sense for the blending application under consideration, only if all the variables in the system have nonnegative values in it. The nonnegativity restrictions on the variables are *linear inequality constraints*. They cannot be expressed in the form of linear equations, and since nobody knew how to handle linear inequalities at that time, they ignored them, and considered this system of equations as the mathematical model for the problem.

Necessary and Sufficient Conditions for the Existence of a Solution

Consider the general system of m equations in the column vector $x = (x_1, \dots, x_n)^T$, of unknowns

$$Ax = b, \quad (1)$$

where $A, b = (b_i)$ are $m \times n, m \times 1$ matrices. The elimination method for solving this system of equations, directly leads to the following classical theorem for the existence of a feasible solution [4].

Theorem 1. *Theorem of alternatives for systems of linear equations: The system of linear equations (1) has no feasible solution x iff there is a linear combination of equations in it which becomes the fundamental inconsistent equation " $0 = 1$;" that is, it has no solution iff there exists a row vector $\pi = (\pi_1, \dots, \pi_m)$ such that*

$$\begin{aligned} \pi A &= 0, \\ \pi b &= \alpha \neq 0, \end{aligned} \quad (2)$$

where α is some nonzero number (e.g., $\alpha = 1$). In linear algebra, the system (2) is known as the alternate system corresponding to Equation (1); it shares the data in the original system (Eq. 1).

That is why when Equation (2) has a feasible solution, any solution of it, π , is known as a *certificate of infeasibility* for the original system (Eq. 1).

The Gaussian and the Gauss–Jordan Elimination Methods

The elimination method for solving systems of linear equations remained unknown in Europe until Gauss rediscovered it at the beginning of the nineteenth century while calculating the orbit of the asteroid Ceres based on recorded observations in tracking it earlier. It was lost from view when the astronomer tracking it, Piazzi, fell ill. Gauss got the data from Piazzi, and tried to approximate the orbit of Ceres by a quadratic formula using the data. He designed the *method of least squares* for estimating the best values for the parameters in the formula, to give the closest fit to the observed data; this gives rise to a system of linear equations to be solved. He rediscovered the elimination method to solve that system. Even though the system was quite large for hand computation, Gauss's accurate computations helped in relocating the asteroid in the skies in a few months' time, and his reputation as a mathematician soared.

Gaussian elimination method and *Gauss–Jordan (GJ) elimination method* are two commonly used variants of the elimination method for solving systems of linear equations such as Equation (1); they are still the leading methods in use today. When applied on a system of linear equations (Eq. 1), both of them will terminate by either finding a feasible solution x of the original system or a certificate π (feasible solution for the alternate system (Eq. 2)) establishing that the original system of Equation (1) is infeasible.

LACK OF A METHOD TO SOLVE LINEAR INEQUALITIES UNTIL MODERN TIMES

Even though linear equations had been conquered thousands of years ago, systems of linear inequalities remained inaccessible until modern times. The set of feasible solutions to a system of linear inequalities is called a *polyhedron* or *convex polyhedron*, and geometric properties of polyhedra were studied by the Egyptians earlier than 4000 BC while building the pyramids, and later by the Greeks, Chinese, Indians, and others.

The following theorem [4] relates systems of linear inequalities to systems of linear equations.

Theorem 2. *Consider the system of linear inequalities*

$$Ax \geq b, \quad (3)$$

where $A = (a_{ij})$ is an $m \times n$ matrix and $b = (b_i) \in R^m$. Let A_i denote the i th row vector of A . So, the constraints in the system are $A_i x \geq b_i$, $i \in \{1, \dots, m\}$. If this system has a feasible solution, then there exists a subset $P = \{p_1, \dots, p_s\} \subset \{1, \dots, m\}$ such that every solution of the system of equations

$$A_i x = b_i, i \in P,$$

is also a feasible solution of the original system of linear inequalities (Eq. 3).

This theorem states that every nonempty polyhedron has a nonempty face that is an affine space. It can be used to generate a finite enumerative algorithm to find a feasible solution to a system of linear constraints containing inequalities. It involves enumeration over subsets of the inequalities in the system. For each subset do the following: eliminate all the inequality constraints in the subset from the system. If there are any inequalities in the remaining system change them into equations. Find any solution of the resulting system of linear equations. If that solution satisfies all the constraints in the original system, terminate. Otherwise, repeat the same procedure with the next subset of inequalities. At the end of the enumeration, if no feasible solution of the original system has turned up, it must be infeasible.

However, if the original system has m inequality constraints, in the worst case this enumerative algorithm may have to solve 2^m systems of linear equations before it either finds a feasible solution of the original system, or concludes that it is infeasible. The effort required grows exponentially with the number of inequalities in the system in the worst case, so it is not practical. But this theorem presents an interesting *paradox* about whether systems of linear equations,

or systems of linear inequalities, are more fundamental.

As you know, linear equations can be transformed into linear inequalities by replacing each equation with the opposing pair of inequalities; but there is no way a linear inequality can be transformed into linear equations. This indicates that linear inequalities are more fundamental than linear equations.

But this theorem shows that linear equations are the key to solving linear inequalities, and hence are more fundamental. This is the paradox.

THE IMPORTANCE OF LINEAR INEQUALITY CONSTRAINTS, AND THEIR RELATION TO LINEAR PROGRAMS

The first interest in inequalities arose from studies in mechanics, beginning in the eighteenth century. Crude examples of applications involving linear inequality models started appearing in published literature around the 1700s.

Linear programming (LP) involves optimization of a linear objective function subject to linear inequality constraints. Examples of LP models started appearing in published literature from about the middle of the eighteenth century. An example of an application of LP is the fertilizer maker's product mix problem discussed in Ref. 4. It leads to the following LP model

$$\begin{array}{ll} \text{Maximize } z(x) = 15x_1 + 10x_2 & \text{Item} \\ \text{Subject to} & \\ & 2x_1 + x_2 \leq 1500 \text{ RM 1} \\ & x_1 + x_2 \leq 1200 \text{ RM 2} \\ & x_1 \leq 500 \text{ RM 3} \\ & x_1 \geq 0, x_2 \geq 0 \end{array}$$

in which the decision variables x_1, x_2 are the tons of high-pH, low-pH fertilizers manufactured per day using three raw materials RM 1, 2, 3 for which the available supply is at most 1500, 1200, 500 tons/day, respectively. The limit on the supply of each of these raw materials leads to a constraint in the model; that is why these raw materials are called the *items* corresponding to those constraints in the model. The objective function to be

maximized is the daily net profit from fertilizer manufacturing activities.

In this example, all the constraints on the variables are inequality constraints. In the same way, inequality constraints appear much more frequently and prominently than the equality constraints in most real-world applications. Before the advent of LP, linear equations were used to model problems, mostly because an efficient method to solve them is known.

Fourier was one of the first to recognize the importance of inequalities as opposed to equations for applying mathematics. Also, he was a pioneer who, in the early nineteenth century, observed the link between linear inequalities and linear programs.

Necessary and Sufficient Conditions for the Existence of Feasible Solutions to General Systems of Linear Constraints

The problem of finding a feasible solution to a general system of linear constraints: $Ax = b$, $Dx \geq d$; can itself be posed as a linear program through a Phase I formulation (see any of the Refs 4 to 8) and by solving this Phase I linear program, we can obtain a feasible solution for the system if the system is feasible, or obtain a certificate of infeasibility for it (similar to the one discussed for systems of linear equations in the section titled "Mathematical Modeling, Algebra, Systems of Linear Equation, and Linear Algebra").

Associated with every LP problem, there is another linear program called its *dual*, involving a different set of variables but sharing the same data. When referring to the dual problem of an LP, the original LP is called *the primal* or *the primal problem*. Together, the two problems are referred to as a *primal, dual pair* of linear programs. The names *primal, dual* for the two problems were coined by Tobias Dantzig, father of George Dantzig, around 1955 in conversations with his son.

A duality-type result for systems of linear equations only (no inequalities) is Theorem 1 discussed above, has been known for a long time (by the eighteenth century or even earlier) but similar results for systems of linear constraints including linear inequalities were unknown until recently. These

important duality-type results for systems of linear constraints including inequalities, known as *either/or theorems* or *theorems of alternatives* started appearing in published literature from the mid-nineteenth century.

These theorems show that a given system of linear constraints has a feasible solution iff another system in a different set of variables but constructed using the same data as the original system, has no feasible solution. The first such necessary and sufficient condition for feasibility of a system involving linear inequalities seems to be that of Gordon, given in an 1873 paper:

Gordon's Theorem. *The system: $Ax < 0$ has a solution iff the alternate system: $yA = 0, y \geq 0$ has no nonzero solution.*

At the end of the nineteenth and the first half of twentieth centuries, many such results were published by Farkas, Minkowski, Stienke, Motzkin, and several others. The most famous among them, that appeared in 1894, is

Farkas' Lemma. *The system $Ax = b, x \geq 0$ has a feasible solution iff the alternate system $yA \leq 0, yb > 0$ has no feasible solution.*

The fundamental notion of *duality* and the term itself, were introduced by von Neumann in conversations with Dantzig in 1947, and stated in a working paper written by him in the same year. Gale, Kuhn, and Tucker independently formulated the duality theorem of LP and proved it rigorously using Farkas' lemma in 1951; and they received the John von Neumann Theory prize of INFORMS in 1980 for this work.

Duality plays a big role in LP theory. One of the corollaries of the duality theorems of LP is that the general linear program

$$\begin{aligned} &\text{Minimize } cx & (4) \\ &\text{subject to } Ax = b \\ &\text{and } Dx \geq d \end{aligned}$$

and the system of linear constraints

$$\begin{aligned} Ax &= b, \\ Dx &\geq d, \\ \pi A + \mu D &= c, \\ cx - \pi b - \mu d &\leq 0, \\ \mu &\geq 0, \end{aligned} \tag{5}$$

are mathematically equivalent problems, in the sense that $\bar{x}$ is an optimum solution of Equation (4) iff there exists a $(\bar{\pi}, \bar{\mu})$ such that $(\bar{x}, \bar{\pi}, \bar{\mu})$ is feasible with respect to Equation (5) and conversely if $(\bar{x}, \bar{\pi}, \bar{\mu})$ is any feasible solution to Equation (5), then $\bar{x}$ is an optimum solution of the original LP Eq. (4), and $(\bar{\pi}, \bar{\mu})$ is an optimum solution of the dual of the LP Eq. (4) [4].

This corollary of the duality theorems shows that any linear program can be posed as a problem of solving a system of linear inequalities without any optimization. Thus, solving linear inequalities and LPs are mathematically equivalent problems. Both problems of comparable sizes can be solved with comparable efficiencies by available algorithms. So, the additional aspect of "optimization" in linear programs does not make LPs any harder either theoretically or computationally.

FOURIER ELIMINATION METHOD FOR LINEAR INEQUALITIES

By 1827, Fourier generalized the elimination method to solve a system of linear inequalities. The method now known as the *Fourier* or *Fourier–Motzkin elimination method*, is one of the earliest methods proposed for solving systems of linear inequalities. It consists of successive elimination of variables from the system. However, starting with a system of m inequalities, the number of inequalities can jump to $O(m^2)$ after eliminating only one variable from the system, so this method is not practically viable except for very small problems.

HISTORY OF THE SIMPLEX METHOD FOR LP

In 1827, Fourier also published a geometric version of the principle behind the simplex algorithm for an LP (vertex-to-vertex descent along the edges to an optimum, a rudimentary version of the simplex method) in the context of a specific LP in three variables (an LP model for a Chebyshev approximation problem) but did not discuss how this descent can be accomplished computationally on systems stated algebraically. In 1910, De la Vallée Poussin designed a method for the Chebyshev approximation problem that is an algebraic and computational analog of this Fourier's geometric version; this procedure is essentially the primal simplex method applied to that problem.

In a parallel effort, Gordon (in 1873), Farkas (in 1896), and Minkowski (in 1896) studied linear inequalities and laid the foundations for the algebraic theory of polyhedra and derived necessary and sufficient conditions for a system of linear constraints including linear inequalities to have a feasible solution.

Studying LP models for organizing and planning production, Kantorovich (in 1939) developed the idea of dual variables (*resolving multipliers*) and derived a dual-simplex type method for solving a general LP.

Full citations for references before 1939 mentioned so far can be seen from the list of references in Refs 5 and 6.

This work culminated in the mid-twentieth century with the development of the primal simplex method by Dantzig. This was the first complete, practically and computationally viable method for solving systems of linear inequalities. So, LP can be considered as the branch of mathematics which is an extension of linear algebra to solve systems of linear constraints including linear inequalities. The development of LP as a decision making tool is a landmark

event in the history of mathematics, and its application brought our ability to solve general systems of linear constraints (including linear equations, inequalities) to a state of completion.

Now the simplex method is one of the popular methods for solving either systems of linear constraints including linear inequality constraints, or linear programs. The primary computational tool used by the simplex method for solving an LP is the same one used in the GJ elimination method for linear equations (the GJ Pivot step on the detached coefficient table of the problem), hence the simplex method can be viewed as the extension of the GJ method for solving systems of linear equations to systems of linear constraints including inequalities or LPs.

LP has now become a dominant subject in the development of efficient computational algorithms, the study of convex polyhedra, and in algorithms for decision making. But for a short time in the beginning, its potential was not well-recognized.

Dantzig tells the story of how when he gave his first talk on LP and his simplex method for solving it at a professional conference, Hotelling dismissed it as unimportant "since everything in the world is nonlinear." But von Neumann came to the defense of Dantzig saying that the subject will become very important (see p. xxvii of Ref. 7). The preface in this book contains an excellent account of the early history of LP.

von Neumann's early assessment of the importance of LP turned out to be astonishingly correct. Today, the applications of LP in almost all areas of science are so numerous, so well known, and recognized that they need no enumeration. Also, LP seems to be the basis for most of the efficient algorithms for many problems in other areas of mathematical programming. Many of the successful approaches in nonlinear programming, discrete optimization, and other

Linear Algebra

→

Linear Programming

Study of linear constraints including inequalities. Twentieth century extension of linear algebra.

branches of optimization are based on LP in their iterations. Also, with the development of duality theory and game theory, LP has assumed a central position in economics.

Using the revised simplex algorithm, by the 1960s, Dantzig and Wolfe had developed *column and row generation techniques* for solving LP models without having all the constraints explicitly on hand, but generating each column (or row) vector in the model as needed; see Ref. 5 for details.

WORST-CASE COMPUTATIONAL COMPLEXITY OF THE SIMPLEX METHOD AND OF LP

By 1970, software systems for LP based on the simplex method were well developed and were able to handle very satisfactorily even the largest LP models appearing in applications in those days. So, at that time, everyone considered LP as a well-solved problem, and the simplex method was the ultimate most efficient algorithm for solving it. No one expected any further significant algorithmic developments in LP.

But small groups of theoretical researchers in several centers were busy trying to determine the worst-case computational complexity of the simplex method (i.e., whether it is a polynomial-time algorithm or not), and of LP itself (i.e., whether it belongs to the class P of polynomially solvable problems or not). Then, around 1970, Klee and Minty constructed a class of LPs with $2n$ constraints in n variables $(x_1, \dots, x_n)^T$ for each $n \geq 2$, with the feasible region for the n th problem being a slightly perturbed unit cube of dimension n having 2^n extreme points, and showed that the problem of maximizing x_n in it by a version of the simplex method takes $2^n - 1$ pivot steps to solve. So, to solve the n th problem in this class, this version of the simplex method passes through every extreme point of the feasible region before terminating with the unique optimum solution of the problem. This has conclusively established that even though the simplex method solves LP models very efficiently in practice, at least this particular version of it is not a polynomial-time algorithm in the worst case [8].

By now (2009) all popular versions of the simplex method for LP have been shown to require exponential time effort in the worst case. The question “is there a version of the simplex method for LP that is a polynomial-time algorithm?” remains an unresolved theoretical research problem in LP.

Ever since the work of Klee and Minty, the question “is there a polynomial-time algorithm for LPs?” became a challenge for algorithmic researchers. This challenge was settled with an affirmative by a young Russian mathematician, Leonid Khachiyan, in 1979. He developed the ellipsoid method for LP and showed that the computational effort to solve an LP of size L in n variables using it is bounded above by $O(n^4 L)$; thus establishing that the ellipsoid method is a polynomial-time algorithm for LP. Even though in practice the computational performance of the ellipsoid method is very poor in comparison with the simplex method, Khachiyan’s result established that LP belongs to the class P and ushered in the era of polynomial-time methods for LP [8].

For finding a feasible solution to a system of linear inequalities, like the simplex method, the ellipsoid method also has the remarkable property that it does not need all the constraints in the model explicitly but only a scheme for checking at each stage whether the current iterate is feasible, or a constraint in the model that it violates.

DEVELOPMENT OF INTERIOR POINT METHODS FOR LP

In Ref. 9, Dikin published the first interior point method (IPM) for LP, this method has subsequently been named as the *affine scaling method*. Dikin proved convergence results on this method in a subsequent publication in 1974. But his papers went unnoticed until the event mentioned in the next paras.

It is still not known whether the affine scaling method for LP is a polynomial-time algorithm.

In the early 1980s, Narendra Karmarkar pioneered a new polynomial-time method for LP, an IPM, which claims to be many times faster than the simplex method for solving

large-scale sparse LPs. These claims helped to focus researchers' attention on it. His work attracted worldwide attention, and his talks on it at that time stimulated a lot of work on these methods that stay "away" from the boundary of the feasible region.

In the flush of Karmarkar's international fame, his company at that time, AT&T saw a lucrative business opportunity. They started a small division with several high-level programmers to develop software for Karmarkar's algorithm for LP. Soon they put on the market a bundled system including a computer and software under the trade name *Korbex system* for 8 or 9 million dollars. I believe that they have been able to sell only a couple of systems, because soon after Karmarkar's result became known, many researchers developed IPMs for LP much more efficient than Karmarkar's algorithm, and released software based on these algorithms as free downloads. So, within a very short time the Korbex division of AT&T was closed and the remaining units of the Korbex system were mothballed.

In the tidal wave of research that ensued many different classes of IPMs, barrier algorithms, and central path approaches have been developed for LP and extended to wider classes of problems including convex quadratic programming, monotone linear complementarity problem, and semidefinite programming problems. Among the many IPMs, the *primal-dual IPM*, has become the most popular IPM for solving LPs and LP software implementations.

This primal-dual IPM has been observed to take much smaller number of iterations to solve LPs than the simplex method, and this number grows very slowly with the size of the LP model being solved, with the result that IPMs have gained the reputation of *taking almost a constant number of iterations* even as the size of the LP grows. Now, most large-scale LPs are typically solved using software based on IPMs, commercial solvers of LP like CPLEX are able to solve models arising in applications very fast (a few minutes of CPU time) and thus, meet the needs of practitioners very satisfactorily.

But the simplex method has some subtle advantages too. It is an ideal method for solving small LPs by hand. The IPMs on the other hand, are not suitable for hand computation even on small LPs. Another is that if the LP being solved has an optimum solution, then at termination the simplex method outputs an optimum basic feasible solution (BFS) even when the LP has alternate optimum solutions. On LPs with alternate optimum solutions, the IPMs will output a relative interior point of the optimum face and not a BFS; to move from that point to an optimum BFS requires additional computation. Practitioners typically seem to prefer an optimum BFS over a relative interior point of the optimum face for implementation in real-world applications.

NEWER METHODS TO SOLVE LPS USING MATRIX INVERSION OPERATIONS SPARINGLY

All the methods discussed so far, which are based solely on matrix inversion operations, work very well if the models are very sparse, and their performance depends critically on being able to exploit the sparsity in the model to advantage. For solving large-scale models which do not fit this mold, these methods have difficulty.

So, recent algorithmic research on LP has focused on the methods that can solve LPs fast without using matrix inversion operations, or using them only sparingly. Also, in the methods discussed above, every constraint in the model appears in the matrix inversion operations carried out in every step. If the new methods operate with only a subset of constraints selected intelligently in matrix inversion operations in each step, they may have an advantage. The future of algorithmic research in LP is in this area sphere methods discussed in [4,10,11] are in this category.

HOLT–WINTERS EXPONENTIAL SMOOTHING

RONG PAN

School of Computing, Informatics, Decision
Systems Engineering, Arizona State
University, Tempe, Arizona

The Holt–Winters method is a class of forecasting procedures for time series with trend and seasonality. It was initially developed based on empirical evidence and intuitive reasoning. Over decades its statistical properties and practical power have been discovered and tested by numerous studies [1–3]. Besides being simple and practical, the Holt–Winters method and its variants are remarkably robust for a wide range of applications. Today, it is one of the most popular forecasting systems employed in demand forecasting, production planning, inventory control, and so on.

During the 1950s, Holt developed an exponential smoothing method for additive trends and seasonal data. His work was originally reported to the Office of Naval Research in 1957 and was recently reprinted in *International Journal of Forecasting* [4]. Winters [5] tested Holt’s method with empirical data, and this method and its variants became known as the *Holt–Winters forecasting system*.

Throughout this article, x_t will be used to denote both a time series and its parent stochastic process, $\hat{x}_t(k)$ to denote a k -step-ahead forecast from time t . The remaining paper is organized as follows: first, an example will be given for illustrating the trend and seasonal components commonly appeared in time series, followed by the description of the additive and multiplicative versions of the Holt–Winters method. Then, the estimation method of smoothing parameters and the diagnosis of forecasting method are discussed. The software implementation of the Holt–Winters method is described. Finally, some further developments of the Holt–Winters method are presented.

EXAMPLE: AIRLINE PASSENGER DATA

The following time series (Fig. 1) shows the totals of international airline passengers from January 1949 to December 1960 (12 years, 144 observations). Data are collected monthly and are listed as Series G in Brown [6]. The series clearly shows seasonal pattern—more traffic in July and August but less in November—and an increasing trend. It also shows that the amplitude of the cycle enlarges over years.

After a natural logarithm transformation of the data, the series is identified as a seasonal ARIMA (0,1,1)X(0,1,1)₁₂ in Box *et al.* [7]. The forecasts of the passenger amount in the last two years (Years 1959 and 1960) as well as one year in future according to this model are plotted in Fig. 2a. One can see that the cyclical feature has been captured by the model, but the modeled increasing trend and increasing amplitude of cycle are lower than expected. Figure 2b shows the forecasts using the Holt–Winters method using the original data set with three smoothing parameters as 0.323, 0.045, and 0.980. It appears that the result of the Holt–Winters method is better than the previous one. The mean square error of the ARIMA method calculated for the last 2 years (January 1959–December 1960) is 1706. The mean square error of the Holt–Winters method is 1434.

HOLT–WINTERS METHOD

The Holt–Winters forecasting method is a heuristic decomposition procedure for seasonal data. It decomposes the forecast of a time series to three components—level, trend, and seasonal. The estimations of these components are updated by applying exponential smoothing technique (See, *The Exponentially Weighted Moving Average*). Therefore, there are three smoothing parameters and they are determined either *a priori* or by fitting historical data. Depending on the types of trend and seasonal components, the Holt–Winters

Figure 1. Monthly international airline passenger (in thousands).

forecasting method can be specified as for a time series of linear trend, exponential trend, or damped trend, and additive seasonal or multiplicative seasonal, and any combination of trend and seasonal. In this section we will describe two basic Holt–Winters forecasting procedures for linear trend with additive seasonality and linear trend with multiplicative seasonality. For other variants of the Holt–Winters method, one may refer to Ref. 1. In general, if the amplitude of the

seasonal pattern is independent of the level, then an additive model is appropriate; however, if the amplitude of the seasonal pattern is proportional to the level, a multiplicative seasonal effect needs to be considered.

The basic Holt–Winter model assumes a linear trend. Adopting the notations used in most textbooks and literature, we write the forecasting procedure as the following for the additive seasonal version of the

Figure 2. Forecasting using (a) ARIMA (0,1,1)X(0,1,1)₁₂ model and (b) the Holt–Winters method.

Holt–Winters method:

$$L_t = \alpha(X_t - S_{t-p}) + (1 - \alpha)(L_{t-1} + T_{t-1}), \quad (1)$$

$$T_t = \beta(L_t - L_{t-1}) + (1 - \beta)T_{t-1}, \quad (2)$$

$$S_t = \gamma(X_t - L_t) + (1 - \gamma)S_{t-p}, \quad (3)$$

where L_t is the level component, T_t the trend component, and S_t the seasonal component; α , β , and γ are exponential smoothing parameters. Let p be the length of cyclical period and k be the forecasting lead time. The k -step-ahead forecast of a time series and the one-step-ahead forecasting error are given by

$$\hat{x}_t(k) = L_t + kT_t + S_{t+k-p} \quad (4)$$

and

$$e_t = x_t - (L_{t-1} + T_{t-1} + S_{t-p}), \quad (5)$$

respectively.

For the multiplicative seasonal version,

$$L_t = \alpha(X_t/S_{t-p}) + (1 - \alpha)(L_{t-1} + T_{t-1}), \quad (6)$$

$$T_t = \beta(L_t - L_{t-1}) + (1 - \beta)T_{t-1}, \quad (7)$$

$$S_t = \gamma(X_t/L_t) + (1 - \gamma)S_{t-p}, \quad (8)$$

$$\hat{x}_t(k) = (L_t + kT_t)S_{t+k-p}, \quad (9)$$

and

$$e_t = x_t - (L_{t-1} + T_{t-1})S_{t-p}. \quad (10)$$

It is well known that the underlying optimal model of the additive version of the Holt–Winters method is an ARIMA time series model. By optimal, we mean that the additive Holt–Winters method provides the minimum one-step-ahead mean square error forecasting for the underlying ARIMA model. The discussion of the equivalency of exponential smoothing and the models to certain types of ARIMA models can be found in Roberts [8]. However, the multiplicative Holt–Winters method does not have an ARIMA equivalent, because it is a nonlinear forecasting method in nature. Even for the additive Holt–Winters method, Chatfield [9] argued that its ARIMA equivalent is so complex that the model identification through

the time series’ autocorrelation structure becomes impossible. Recent theoretical development has shown that exponential smoothing methods are optimal for a very general class of state–space models, which is broader than the ARIMA class.

It has long been criticized that the Holt–Winters method, as a heuristic, does not have a solid theoretical foundation, which, in turn, hampers the identification of a time series that could be best forecasted by the Holt–Winters method. In fact, using the Box–Jenkins methodology [7], most time series generated from the additive Holt–Winters models cannot be correctly identified. Gardner [1] summarized a practical identification procedure. First, we plot the series and look of trend, seasonal variation, outliers, and changes in structure that may be slow or sudden and may indicate that exponential smoothing is not appropriate in the first place. We should examine by outliers, consider making adjustments, and then decide on the form of the trend and seasonal variation. We should also consider the possibility of transforming the data, either to stabilize the variance or to make the seasonal effect additive. Next, we fit an appropriate method, produce forecasts, and check the adequacy of the method by examining the one-step-ahead forecast errors, particularly their autocorrelation function. The finding may lead to a different method or a modification of the selected method.

Empirical studies have shown that the Holt–Winters forecasting system is robust at short horizons, but tends to overshoot the data at longer horizons (more than three or four time periods ahead); so it may be advisable to damp a linear trend at long horizons. Parzen [10] tackled the problem by creating “short-memory” forecast and “long-memory” forecast, where the “short-memory” utilizes the autocovariance of stationary time series and the “long-memory” contains a nonstationary trend component. Lewandowski’s FORSYS program [11] added the damped trend as the lead time increases and the rate of damping increases with the level of noise. Gardner and McKenzie [12] discussed a generalization of the Holt model with

damped trends to avoid the overshoot of forecast over long lead time. Their study showed that this method improves long-term forecast accuracy compared to the traditional Holts method, while it does not lose much power in short-term forecast.

FITTING TIME SERIES AND FORECASTING

The smoothing parameters used in the Holt–Winters method can be determined by data analysts based on their experience. It is often suggested that the smoothing parameter value should be in the range of 0.1–0.3. However, many studies [13] found that the values of α and γ often exceed 0.3, but the value of β is frequently less than 0.1. One of the common practices of fitting a time series is to find the parameter values that minimize the sum of the squares of the one-step-ahead forecast errors (SSE), that is,

$$\text{Min}_{\alpha, \beta, \gamma} \sum_t e_t^2 \quad (11)$$

$$\text{S.T. } 0 \leq \alpha, \beta, \gamma < 1.$$

Some other optimization criteria, such as minimizing mean absolute percentage error (MAPE) or mean absolute deviation (MAD), have also been used, but they are not as popular as SSE. Since the additive Holt–Winters model has the ARIMA equivalence, the prediction can be written as a linear combination of past observations, that is, $\hat{x}_t(1) = \phi_t x_t + \phi_{t-1} x_{t-1} + \dots + \phi_1 x_1$. The coefficients in the autoregressive function are functions of the three smoothing parameters. Therefore, the optimal parameter values can be found using the standard method such as the conditional likelihood method [7]. In the multiplicative model, the forecast depends on the past values of the series in a nonlinear manner. Typically numerical search algorithms are required for finding the optimal parameter values.

Finding the optimal smoothing parameters can be a difficult task. According to Ref. 14, this is due to (i) the fitting criteria, such as likelihood functions, being highly nonlinear functions of the parameters and (ii) the likelihood functions not required to

be concave so that the numerical optimization routines cannot guarantee global optima without a full grid search. Snyder and Shami [14] proposed a parsimonious model, which contains only two smoothing parameters and has certain advantages in simplifying parameter estimation. Smoothing parameters are typically restricted to the (0,1) interval. However, McClain [15] and Sweet [16] showed that some parameter values in this interval produce noninvertible models, that is, the impact on forecasts of values in the distant past is larger than for recent values. This is counterintuitive and may produce poor forecasts. Archibald [17] used a parameter space, which is a subset of the additive invertible region, to avoid this problem. With proper approximation, the multiplicative model can be handled in this way too.

The Holt–Winters method has been implemented in many statistical software packages. In Minitab v14 (Time Series $\rightarrow$ Winters' Method), one has to specify the smoothing parameter values *a priori*. Minitab only implements the Holt–Winters method with known smoothing parameters. In SAS, the FORECAST procedure can be used while specifying “method = WINTERS” (for the multiplicative method) or “method = ADDWINTERS” (for the additive method). The Time Series Forecasting System (a graphical data analysis application) in SAS allows one to find the optimal smoothing parameters.

In the remainder of this section, several other issues related to forecasting using the Holt–Winters method are discussed. They include how to find the starting values for recursively estimating the level, trend, and seasonal components (Eqs 1–3 for the additive method and Eqs 6–8 for the multiplicative method); how to normalize seasonal components; how to produce prediction intervals; and the diagnosis of forecasts.

Starting Values

The starting values of level, trend, and seasonal components ($L_0, T_0, S_{1-p}, \dots, S_0$) must be specified at the beginning of the series in order to initiate the updating procedure. The simplest way is to use the average of the observations in the first cycle period, that is,

let $L_0 = \sum_{t=1}^p x_t/p$, $T_0 = 0$ and $S_{t-p} = x_t - L_0$ for the additive version, and $S_{t-p} = x_t/L_0$ for the multiplicative version.

Some researchers suggested using the first two or three cycle periods, instead of one. Some even suggested using the entire observation in calculating the initial values [5,18]. Other less simple methods can be found in Chatfield [13]. Makridakis *et al.* [19] suggested a backcasting method, where the time order of observations is reversed and the most recent data are used to start up the procedure in the reverse direction. The values at the end of the series are then used as the starting values.

Normalization of Seasonal Factor

Seasonal component estimates can be contaminated by some of the other factors being modeled. Because it was observed in practice that seasonal terms are ceasing over time to be simply seasonal effects, many authors have suggested renormalizing the seasonal terms either once a year or at every observation [20].

The seasonal terms are originally set up to reflect the seasonal pattern only; so, in an additive version of the method they should sum to zero and in a multiplicative version they should multiply to one. However, they are not longer so after the calculation over several cycles. Examples have been used to demonstrate that without seasonal factor renormalization, although the forecasts will perform well, the estimates of the individual components (level and seasonal) will be unreliable. The common practice of renormalization is to subtract from each seasonal term a specific amount so that they sum to zero (for the additive version). However, when this renormalization is carried out, forecasts will be biased for the next few periods before the method adjusts level estimates. Therefore, Lawton [21] recommended adjusting the level as well by adding the same amount. Roberts [8] and McKenzie [22] suggested a variant of the Holt–Winters method, which maintains the balance between good forecasts and component estimates and does not require the adjustment of level. The modified seasonal estimate is (for the additive

version)

$$S_t = \gamma \frac{p-1}{p} (x_t - L_t) + \left(1 - \gamma \frac{p-1}{p}\right) S_t(p), \quad (12)$$

$$S_t(j) = S_{t-1}(j-1) - \frac{\gamma}{p} (x_t - L_t - S_{t-1}(p-1)),$$

$$\text{for } 1 \leq j \leq p-1, \quad (13)$$

where $S_t(j)$ is the seasonal estimate at time t for the season which occurred j periods earlier.

Archibald and Koehler [23] put forward a practical method that makes the renormalization equations in a common form. Using state–space equations, they adapted the renormalization equations for the multiplicative version. They recommended that renormalization of seasonal factors should be done in every time period and in the multiplicative version the level and trend should be adjusted along with the seasonal component.

Prediction Intervals

Because the additive Holt–Winters model can be converted to an equivalent optimal ARIMA model, the theoretical result of the prediction interval can be obtained. Yar and Chatfield [24] proposed a method of constructing prediction intervals for the additive Holt–Winters forecasting system. It was extended to the multiplicative version in Chatfield and Yar [25]. It was found that the width of multiplicative prediction intervals will depend on both the lead time and the forecasting time, and it may either decrease or increase with lead time. The exact prediction intervals are complicated and difficult for calculation and comprehension. Oftentimes, simple normal approximations of prediction intervals are employed [26] and the k -step-ahead 95% prediction intervals are given below.

For the additive Holt–Winters method,

$$\left[\hat{x}_t(k) \pm z_{0.025} \sqrt{c_k s^2} \right], \quad (14)$$

where $z_{0.025}$ is the percentile of standard normal distribution; s^2 is the sample variance of prediction errors, $s^2 = \sum_{t=0}^{n-1} (x_{t+1} -$

$\hat{x}_t(1))^{2/(n-3)}$; c_k is a correction factor, $c_1 = 1$, $c_k = 1 + \sum_{j=1}^{k-1} \alpha^2(1+j\beta)^2$ for $2 \leq k \leq p$, $c_k = 1 + \sum_{j=1}^{k-1} [\alpha(1+j\beta) + d_{j,p}(1-\alpha)\gamma]^2$ for $p < k$, and $d_{j,p} = 1$ if j is an integer multiple of p , and 0 otherwise.

For the multiplicative Holt-Winters method,

$$\left[\hat{x}_t(k) \pm z_{0.025} S_{t+k-p} \sqrt{c_k s_r^2} \right], \quad (15)$$

where S_{t+k-p} is the seasonal component of one cycle before; s_r^2 is the sample variance of relative prediction errors, $s_r^2 = \sum_{t=0}^{n-1} [(x_{t+1} - \hat{x}_t(1))/\hat{x}_t(1)]^2/(n-3)$; for the correction factor, $c_1 = (L_t + T_t)^2$, $c_2 = \alpha^2(1+\beta)^2(L_t + T_t)^2 + (L_t + 2T_t)^2$, and $c_k = \alpha^2(1+(k-1)\beta)^2(L_t + T_t)^2 + \dots + \alpha^2(1+\beta)^2(L_t + (k-1)T_t)^2 + (L_t + kT_t)^2$ for $2 \leq k \leq p$.

Monitoring Forecasts

Tracking signal is a tool for monitoring the goodness of a forecasting system. Brown [6] suggested a simple cumulative sum tracking signal. It is a ratio of the cumulative sum of one-step-ahead forecast errors to the smoothed MAD. Trigg [27] suggested a smoothed-error tracking signal. Trigg's signal is simply the ratio of the smoothed error to the smoothed MAD. The value of the signal will fluctuate between 0 and 1. A large signal value indicates that the forecasting system is producing errors that are consistently larger or less than 0; therefore, it is biased.

Directly monitoring one-step-ahead forecasting errors is another common way for

detecting any deficiency of the forecasting system. It is recommended to plot the time series of the errors and their sample autocorrelation and sample partial autocorrelation functions. A good forecasting system will produce random errors, so no pattern is expected from these plots; otherwise, an investigation should be performed to modify the forecast procedure.

SOFTWARE IMPLEMENTATION

We revisit the airline passenger data set, which was discussed in the previous section. The data is taken from Box *et al.* (7, p. 547). By examining the time series plot such as Fig. 1, it is found that a strong increasing trend and the amplitude of seasonal cycle increase along with the trend. Thus, a multiplicative Holt-Winters model is appropriate.

Figure 3a is the command window of the Winter's Method in Minitab. One can select the multiplicative or additive model and specify the seasonal period and parameter values. To generate forecasts, one needs to specify the number of forecasts and the origin time of forecasts. In the "Storage" option, one may select "Forecasts", "Residuals", "Upper 95% prediction limit", "Lower 95% prediction limit", and so on. Note that residuals are the one-period-ahead forecast errors. These residuals are used to calculate MAPE, MAD, and MSD (mean square deviation). These residuals can also be used to generate diagnostic plots using Autocorrelation. After running this model, results are presented in the

Figure 3. The Winter's Method command window in Minitab (a) and outputs (b).

Figure 4. (a) SAS Time Series Forecasting window and (b) Smoothing Model Specification window.

Minitab session window. A snapshot of these results is given in Fig. 3b.

SAS v9.1 also has a graphical interface for time series analysis, which can be found through its top menu, Solutions → Analysis → Time Series Forecasting Systems. The airline passenger data set has already been stored in the SASHELP directory and the data file is named as “air.” In the Time Series Forecasting window, one may select “Develop Models,” then click on the blank and select “Fit smoothing model...” A smoothing model specification window will pop up, where one can choose the Winters’ multiplicative method, as well as weights on level, trend, and season. If “Optimize” is selected, then the optimal weights will be found by using an optimization criterion, such as sum of square error, which is selected in the previous “Develop Models” window. Figure 4 depicts these graphical interfaces.

FURTHER DEVELOPMENT

Irregular Observation Intervals

An *ad hoc* modification of Holt–Winters method with missing observations (irregular observation intervals) was discussed in Cipra *et al.* [28]. The basic idea is to adjust the smoothing parameter values according to the length of intermittent time. The three smoothing parameters used in the Holt–Winters method are modified as

$$V_{t_n} = \frac{V_{t_{n-1}}}{(1 - \alpha)^{t_n - t_{n-1}} + V_{t_{n-1}}}, \quad (16)$$

$$U_{t_n} = \frac{U_{t_{n-1}}}{(1 - \beta)^{t_n - t_{n-1}} + U_{t_{n-1}}}, \quad (17)$$

$$W_{t_n} = \frac{W_{t_{n-1}}}{(1 - \gamma)^{(t_n - t_n^*)/p} + W_{t_{n-1}}}, \quad (18)$$

where α, β, γ are the smoothing parameters used in the Holt–Winters method for regular time series; U, V, W are new smoothing parameters; t_n is the time of observation; and t_n^* is the corresponding time of the same seasonal period as t_n in the last cycle. Note that the time index of an irregular time series, t_n , is the actual time or normalized time, instead of a simple sequence index as used in regular time series.

State–Space Formulation

Ord *et al.* [29] draw the connection of the exponential smoothing method to a general class of state–space models as its underlying optimal model, which is broader than the traditional ARIMA class in that it allows the error variance to depend on the level and seasonal component. The optimal refers to that conditioning on the assumed model for which the exponential smoothing method gives the minimum mean square error forecast. This, in return, explains the robust nature of the Holt–Winters method, which was shown in Chen [30] using Monte Carlo simulation and empirically tested in Makridakis and Hibon [31]. The single source of error (SSOE) state–space models given below are special cases of Refs 29 and 32–34.

For the additive Holt–Winters model, observation equation

$$x_t = L_{t-1} + T_{t-1} + S_{t-p} + \varepsilon_t, \quad (19)$$

state equations

$$L_t = L_{t-1} + T_{t-1} + \alpha \varepsilon_t, \quad (20)$$

$$T_t = T_{t-1} + \alpha \beta \varepsilon_t, \quad (21)$$

$$S_t = S_{t-p} + (1 - \alpha) \gamma \varepsilon_t. \quad (22)$$

The error term ε_t has a value from the normal distribution that has the zero mean and the standard deviation σ .

For the multiplicative Holt–Winters model,

observation equation

$$x_t = (L_{t-1} + T_{t-1}) S_{t-p} (1 + \varepsilon_t), \quad (23)$$

state equations

$$L_t = L_{t-1} + T_{t-1} + \alpha (L_{t-1} + T_{t-1}) \varepsilon_t, \quad (24)$$

$$T_t = T_{t-1} + \alpha \beta (L_{t-1} + T_{t-1}) \varepsilon_t, \quad (25)$$

$$S_t = S_{t-p} + (1 - \alpha) \gamma S_{t-p} \varepsilon_t. \quad (26)$$

Note that, unlike the additive model, in the multiplicative model the variances in three state equations are not constants—they depend on the most recent level and trend components in the level and trend state equations, and the last corresponding seasonal component in the seasonal state equation.

Gardner [2] praised the development of Holt–Winters state–space models as the most significant advancement of this method in recent years. These models can also be easily modified to accommodate damped trends. More recently, the state–space models are utilized in modeling multiple seasonal patterns, such as the daily and hourly patterns of traffic flows [35].

HORSE RACING

JOHN BACON-SHONE
Social Sciences Research Centre,
The University of Hong Kong,
Hong Kong, China

Horse racing is an ancient sport, dating back to Roman times. It has a strong hold in Great Britain and many former British colonies, including Canada, United States, Australia, New Zealand, Hong Kong, India, and Singapore. However, it is also popular in many other countries, including France, Italy, Japan, South Korea, United Arab Emirates, and more. While the most popular form is racing of thoroughbred horses on a flat course, racing over a track with obstacles that require the horses to jump (steeplechase racing) is also popular in some countries and there is also racing where the horses pull people in carts around tracks (known as *trotting*). In all forms of horse racing, the outcome of the race is the rank order of the horses, so only relative time to complete the course matters. Table 1 shows the top 20 countries that had the largest number of races in 2006, according to the worldwide horseracing body, the International Federation of Horseracing Associations [1]. This shows that the United States has by far the largest number of races on the flat (51,491), trots (53,610) and overall (105,278), while Great Britain has the largest number of jump races (3,380). The total number of races in 2006 worldwide was around 320,000, which is over 800 races per day.

In any given horse race, there are usually 6–15 horses competing (although it can be as low as 4 or as high as 40), with prize money usually offered to at least the first three horses. The performance of a horse in a race depends on many variables, including the trainer, the jockey, the distance, the track type and condition, the pedigree, age and condition of the horse, and so on.

Of all the sports, horse racing has attracted the widest range of academic interest from economists, psychologists, statisticians and others studying risk, operational research, and finance, arguably because of the richness of data available from race-tracks across the world for up to a century, allowing detailed analysis of both performance and gambling data from multiple perspectives. The large betting pools mean that successful models can be financially very rewarding. Compared to many financial markets, it has the simplicity of regular known end points. Although often only the aggregate gambling data at the end point is available, for some gambling pools the odds offered on each horse or combination of horses may be publicly available and regularly updated until the start of the race.

GAMBLING

In practice, the major interest in horse racing is because of the gambling, which usually dominates the prize money, although the prize money can be substantial for major races, like the Dubai World Cup, which offers a prize of US\$6 million (about €4 million). Table 2 shows the top 20 countries ordered by the average prize money per race in euros. Hong Kong, UAE, and Singapore rank 1, 2, and 4 on this metric although none of them appear in the top 20 countries ranked on races as shown in Table 1. What is most noticeable is that the prize money per race is usually less than 10% of the betting turnover per race. Although the United States is a clear number one in terms of total races, it is only ranked 3rd on total betting turnover behind Japan and Great Britain and 18th on betting turnover per race. Hong Kong dominates in turnover per race, followed by South Korea, Great Britain, and Ireland. In terms of percentage return to the bettor, Great Britain, Ireland, and Australia are clearly the most generous (88–89%).

Table 1. Total Number of Horse Races in 2006: Top 20 Countries

Country	Flat Races	Jump Races	Trot Races	Total Races
USA	51,491	177	53,610	105,278
Australia	19,821	142	15,666	35,629
Canada	5,281	0	27,183	32,464

In addition to betting on the winning horse, there are many other types of bet on a single race usually available, including identifying any one of the first two or three horses (place or show), the first two horses in finishing order (exacta or perfecta) or unordered (quinella), the first three horses in finishing order (tierce or trifecta) or unordered (trio). There are also often bets that cover two (double), three (treble or pick three), or even up to six races, which usually require identifying all the winners and may have a jackpot that rolls over if there is no winner.

There are two major types of bets, namely, fixed odds bets, usually placed with a bookmaker and variable odds bets, usually placed through a pari-mutuel system that pays out the winning bets pro rata using all of the pool after removing tax and overheads, so that you are in effect gambling against the rest of the bettors rather than a bookmaker. While betting originally required visiting the race-track in order to place the bet, the development of telecommunications and the internet have facilitated the growth of remote betting, so the bettor does not even need to be in the same country and may be in a country where such betting is illegal. Fixed odds bets are now often available not only from bookmakers, but through betting exchanges [2], where other bettors act as the bookmaker and provide the other side of the bet, with the exchanges taking a percentage of the bet. Because offshore bookmakers and betting exchanges can operate while only paying limited tax, they can often offer more attractive odds than onshore operators, although some countries such as the United Kingdom have reduced tax in order to remain competitive. Betting exchanges also usually offer better rates of return than bookmakers as their risk and overheads are usually lower.

PREDICTING THE FINISHING ORDER OF A RACE

Winning a bet requires predicting the outcome of a race. While some gamblers may select bets in a very subjective way, the large money at stake has facilitated the development of sophisticated proprietary models

that incorporate all the information available about the horses, jockeys, trainers, tracks, and so on. The simplest scenario requires predicting the winning horse.

Bolton and Chapman [3] used multivariate logistic regression incorporating 10 horse- or jockey-specific variables, utilizing the discrete choice model of McFadden [4]. What is sometimes missed is that the multinomial logit discrete choice model assumes the “independence from irrelevant alternatives” (IIA). This means that the Bolton and Chapman model, like the model proposed by Harville [5] (which assumes that the performances of the horses expressed in terms of running times follow independent exponential distributions), leads to the conclusion that the chance of horse i beating horse j does not depend on the performance of any other horse. This means that the chance that a horse comes second has a simple relationship to the chance of winning as follows:

$$\begin{aligned} &\Pr(\text{horse } j \text{ comes second} | \text{horse } i \text{ comes first}) \\ &= p_j / (1 - p_i), \end{aligned}$$

where p_i is the chance that horse i comes first. A simpler formulation is in terms of the log odds that horse i beats horse j for k th position, if neither horse comes in the top $k - 1$ positions,

$$LO(i, j|k) = \log(p_i/p_j),$$

which does not depend on k .

This allows modeling the performance not only of the winning horse, but also of all other positions in the race, as it treats each position as a competition amongst all horses that did not finish in an earlier position. However, this would imply that horses compete as strongly for second last place as they do for first place, which is implausible. One way to avoid this problem is to only model the winning position, but that ignores the information about second and third position, where there are clear incentives for the horse and jockey, given the prizes and gambling.

More complex bets also require predicting the second and third placed horses, again raising the question of how the chance of a horse coming second relates to its chance

of winning. Lo and Bacon-Shone [6] summarized different models for the underlying abilities of the horses, which all enable estimation of the probability distribution for the finishing order, given the winning probabilities. Other possible underlying models include the multivariate independent normal distribution proposed by Henery [7] and the generalization of the exponential to the gamma distribution proposed by Stern [8], both of which require numerical solution of a system of integral equations in order to fit the models. Lo *et al.* [9] proposed an extension to the Harville model that provides a good, simple approximation to the Stern and hence the Henery models.

This model assumes that

$$\text{LO}(i, j|k) = \lambda_{k,n} \log(p_i/p_j),$$

where $\lambda_{k,n}$ is decreasing in k and depends weakly on n , the number of horses in the race and the racetrack through the shape parameter in Stern's gamma model, which has Harville's model as the limiting distribution. This model also includes Henery's model as the simplification of $\lambda_{k,n} = 1$. Lo *et al.* [9] showed, using this approximation, that the Henery model fits well for US and Hong Kong data sets, while the Stern model is needed for Japan and that the Harville model does not fit any of the data sets adequately. Lo *et al.* [9] also identified an even simpler approximation, which is that

$$\lambda_{k,n} \approx \mu^k,$$

which fits moderately well in the data sets they examine.

This formulation can be seen as providing guidance how to discount information from lower finishing positions, which is rational given the reducing incentives for lower finishing positions in terms of both prize and gambling returns, without needing to exclude this information completely.

TESTING THE EFFICIENCY OF THE BETTING MARKETS

Betting on horse races has attracted wide interest from economists interested in testing

under what conditions this market is efficient. Ziemba [10] provided a recent review of the well-developed field. Roberts [11] defined efficiency as weak, semistrong, and strong when prices reflect all price, all public, and all information respectively. For weak form efficiency, the initial paper by Griffith [12] found evidence of greater expected returns on horses at shorter odds than those at longer odds for pari-mutuel betting at US tracks (commonly known as the *favorite/long-shot bias*) although he did not do any formal statistical test. Snyder [13] showed statistical evidence that the betting public and newspaper experts both overbet long shots, while Asch *et al.* [14] not only showed statistical evidence of inefficiency in US win pools, with overbet long shots, but also that late bettors have better information, although in all cases the expected return was negative, given the track take. This was replicated in Australia by Bird *et al.* [15] and Dowie [16] in the United Kingdom using bookmaker data, unlike the papers above which were all restricted to pari-mutuel betting. Bird and McCrae [17] also examined the public information in newspaper tipsters odds and the change in bookmaker odds, but did not find any evidence of inefficiency, unless there is prior knowledge of the change in odds.

However, Busche and Hall [18] showed that this inefficiency does not exist in Hong Kong. One possibility is that the large pools in Hong Kong (as seen in Table 2, they are on average more than 50 times the US pools per race and 5 times the Japanese pools per race) have attracted sufficient serious gamblers, like Benter, to remove the bias. Lo and Bacon-Shone [19] used a more sensitive log-odds test instead of grouping by odds or position as used by Busche and Hall. They conclude that Hong Kong and Shanghai have no bias toward long shots, while at least some tracks in the United States and Japan have a positive bias, although Busche [20] showed that other tracks in Japan do not show the bias and Walls and Busche [21] suggest this mixed result in Japan may reflect that tracks showing the bias have much lower turnover than the tracks that show the bias. Walls and Busche [21] also showed that at least

some of the bias in favor of long shots is in fact bias caused by breakage (the rounding down of payouts to the nearest 10 cents).

Interestingly, Smith *et al.* [22] found significant evidence of long-shot bias even in betting exchange data for Great Britain, although the amount of bias was significantly less than for bets with bookmakers.

In recent years attention has focused on trying to identify the underlying source of this bias. In simple terms, the bias can be caused either by a supply issue (i.e., bookmakers protecting themselves against inside information) or demand (bettors who prefer more risky bets). Aggregate data from win bets alone is not sufficient to distinguish between these alternatives.

One key step forward was Shin's papers that developed a model [23] to show how inside knowledge could explain the long-shot preference and then applied [24] that model to Dowie's data, concluding that the incidence of insider trading was around 2%. Shin's model assumes that the bookmakers know that insiders always back the winner, while the proportion of money on all other horses is consistent with the chances of those horses winning and they adjust the odds to derive zero maximal profit. Williams and Paton [25] showed that the evidence of insider trading appears to be much less in higher handicap races, where there is more public information. However, Schnytzer and Shilony [26] showed that Shin's formulation is not sufficient to fully explain the long-shot preference as there is still bias after allowing for the inside information.

One important point is that analyzing pari-mutuel betting alone eliminates supply side explanations and Bruce *et al.* [27] examined a data set that allows segmentation of the pari-mutuel market into three parts: home race track, other racetracks, and off-track betting. They argue that given the travel and admission costs of attending a track and the preference of social gamblers for on-track atmosphere at the home track, there will be differences in the long-shot bias in the three markets. Using the Lo and Bacon-Shone log-odds test mentioned above, they show a positive bias for the home track and negative bias for other tracks and

off-track betting, which they explain as a rational exploitation of the mispriced betting of home track bettors.

This still does not provide conclusive evidence to distinguish between inside information explanations and risk preference explanations. Snowberg and Wolfers [28] investigated this distinction for a large US data set of about 650,000 races. They formulate two extreme positions, unbiased expectations and risk-loving (preferences model) and biased expectations and risk-neutral (perceptions model). The key innovation is that they investigate exacta and other combinatoric bets. Their initial analysis is flawed as it uses the Harville model to predict the conditional probabilities for the horse coming second given the knowledge of the winning horse. However, as noted above, Lo and Bacon-Shone [6] have shown conclusively that for United States, Hong Kong, and Japan (i.e., both in situations that do and do not show the long-shot preference), the Harville model fits second and third place conditional probabilities very poorly and that Stern's independent gamma model fits measurably better. However, Snowberg and Wolfer go on to estimate the conditional probabilities for a grid of combinations of win probabilities for the two horses. Even this approach is arguably flawed as the analysis of Lo and Bacon-Shone showed that for the gamma model the relationship between the win and exacta probabilities depends (although only weakly) on the number of horses in the race. Despite these possible limitations, this paper provides strong evidence that the perceptions model provides predictions of exacta, quinella, and trifecta bets given the win bets that are much more consistent than the preference model. The key remaining question is to explain the Hong Kong anomaly of an anomaly as presented by Busche and Hall [18].

Sung and Johnson [29] reviewed the literature on semistrong efficiency in horse race betting and conclude that while bettors are remarkably successful in discounting relatively simple information, the semistrong form inefficiency observed appears to arise from complex, subtle, and possible changing relationships.

BETTING SYSTEMS FOR HORSE RACING

Hausch *et al.* [30] showed how to use win bet information to take advantage of inefficiencies in the place and show markets. This system combined estimates of place and show probabilities using Harville's model and the optimal capital growth model of Kelly [31] to select the bet sizes to maximize asymptotic growth of capital. This criterion yields a relative bet size of

$$b = (t_p - 1)/(t - 1),$$

where p is the estimate for the bet to win, t is the gross return and the bet is placed if t_p is greater than one. Hausch and Ziemba [32] extended the system to cover multiple horses, multiple bets, and account for breakage and take. Gramm and Ziemba [33] summarized subsequent improvements made to their system, including breeding and performance data on the horses. Hausch and Ziemba [34] focused specifically on risk-free hedges (referred to as a *lock* in horse racing) and identified that for pools that require a minimum payout on show bets, a heavily backed favorite can provide a lock in the show market.

Bolton and Chapman [3] not only developed estimation procedures for predicting horse performance, they also combined it with various betting strategies to see if they would yield a profit, given the semistrong form inefficiencies known to exist. Although their strategies were better than a random strategy, they were unable to achieve a profit. Chapman and Winchester [35] tried the model on a larger sample of 2000 Hong Kong race data and concluded that a profit was possible.

Details of a successful gambling system built on the Bolton and Chapman model can be found in the two papers by Benter [36,37]. This system also used the ideas of Hausch [30] *et al.* and Lo *et al.* [9], although it also contained an important innovation in that Benter used a two-stage process. Firstly, he used multivariate linear regression of the finishing position (normalized to the $[-0.5, +0.5]$ interval) on all the performance data he collected on horses, trainers, and jockeys.

He then applied these regression coefficients to construct a performance estimate for each horse in a race and fit the Bolton and Chapman type model to the linear combination of this performance estimate and the public log odds for the horse to win that race in order to estimate the weights in the linear combination.

Edelman [38] has recently examined replacing the first regression stage of Benter's approach with the Support Vector Machine (SVM) of Hearst *et al.* [39] and showed that he can generate profits on a 100-race holdout sample taken from a small sample of only 200 races in Australia, outperforming the linear regression approach of Benter and a feedforward Neural Network model. Lessman *et al.* [40] revisited Edelman's approach, but they only use a binary win-lose outcome in the first SVM stage instead of the normalized finishing position. They then apply their approach to 400 races from Great Britain with a holdout sample of 156 races for evaluation. They illustrate that their model generates higher profits than Edelman's approach, which in turn generates higher profits than the original approach of Bolton and Chapman. However, they exclude information on positions other than winning, on the grounds that the distribution of second place is different from first place. This argument is flawed given the results of Lo *et al.* [9] mentioned above which show that although positions other than winning provide less information, they do contain valuable information, even if Edelman's model did not take full advantage of that information.

BETTING TURNOVER FOR HORSE RACES

While the total money bet on a race is not of direct interest to many gamblers, it is clearly of great interest to bookmakers, operators of pari-mutuel pools, and governments receiving tax revenue as it has direct impact on their revenues. It is also of interest to large-scale gamblers as large bets can change the payouts substantially in smaller pools. It is also of interest in understanding the impact of changes in the regulatory regimes and

of the competitiveness of horse racing with other forms of leisure activity.

Thalheimer and Ali [41] reviewed evaluations of the competition with pari-mutuel betting on horse races from within and outside the industry. Total turnover of pari-mutuel wagering on horse racing declined 44% from 1977 to 2002. They show that competition from casino gaming has had a significant negative impact, while slot machines inside pari-mutuel betting shops also reduces the turnover. They also show negative impacts from state lotteries and a professional sporting event. While simulcasts reduce the local turnover, there is evidence of increased total pari-mutuel turnover. However, their analysis looks primarily at gross turnover at the daily or monthly level.

In terms of betting at the race level, Ray [42] examined the predictors of pari-mutuel betting turnover for just 200 individual races across a one-month period at a single track, which greatly limits generalizability. Her model has an R^2 of about 64%. Gramm *et al.* [43] examined 2,957 races across 12 US racetracks from October to December 2002. Their data covers from five to nine different pools on each race. Their regression model for log of total turnover has an unadjusted R^2 of about 82% and shows increases with an increase in betting pools, more horses, more competitive races, later races, and larger prizes. While they also examine separate models for win, place, show, exacta, and trifecta pools, they do not directly examine the distribution of money across pools. Bacon-Shone and Woods [44] provided the most detailed study within location (5271 races at two tracks over seven seasons from 2000 to 2007). They include economic (employment), meteorological (humidity, temperature, and rainfall), and race data. Their model yields an adjusted R^2 of about 84% for the log of total turnover for nine pari-mutuel pools, with increases for lower class, more horses, middle distances, later races, less rain, races earlier in the week. They also show the impact of a rebate on losing win bets of 10% on losing bets of at least HK\$10,000 in the win, place, quinella, and quinella-place pools introduced at the start of the 2006 season. They also examine

the distribution of money between pools eligible for the rebate and other pools. This shows that the increased bet options move money away from the rebate pools, as does a strong first or second favorite, while the introduction of the rebate moved money back to the rebate pools.

CONCLUSION

In summary, horse racing data continues to yield fascinating research that provides insight into the efficiency of markets and what determines human behavior and horse performance as well as the development of sophisticated consumer choice models that will undoubtedly be utilized in many other fields that are also rewarding, even if not as financially rewarding as gambling.

Interesting future research directions include identifying better models for the finishing order of horses that incorporates explicitly the discounting for lower positions; confirmation that the perceptions model is more consistent generally with gambling data than the preference model, including in Hong Kong where the long-shot bias is absent; further examination of the returns when using SVM modeling; and examining whether efficiency of betting on horse races is increasing over time, given the wide availability of sophisticated models to assist gamblers and the increasing role of gambling exchanges.

HOUSING AND COMMUNITY DEVELOPMENT

MICHAEL P. JOHNSON
Department of Public Policy and
Public Affairs, University of
Massachusetts Boston,
Boston, Massachusetts

Housing is a key component of the US economy: in 2001, housing comprised more than a third of the nation's tangible assets, and housing consumption and related spending represented more than 21% of the US gross domestic product [1]. Housing that is of a decent quality and *affordable* is associated with increased household wealth, family stability, mental and physical health, labor market participation, educational achievement, and neighborhood quality [2]. Decent and affordable housing also contributes to the improved physical, economic, environmental, and social health—the *sustainability*—of communities. These impacts are especially important for lower-income and disadvantaged households.

However, the benefits of housing, and of sustainable communities, are unequally distributed. Examples include increases in renters in market-rate housing paying excessive fractions of incomes in rent or living in severely substandard housing [3], shortages in affordable and “workforce” housing [4], flat or declining funding levels for public housing authorities [1], persistent gaps in homeownership rates by race and ethnicity [5], excessive housing and transportation burdens on working families [6–8], challenges in economic revitalization facing older urban centers [9], and displacement of the urban poor as a consequence of public housing renovation and economic renewal [10]. These concerns are summarized as inequalities across class, race, and ethnicity in the “geography of opportunity” linking housing, education, employment, and other services [11].

Most recently, the US economic recession of 2007–2009 [12] has had adverse effects across the economy, particularly residential housing. Since 2005, there have been substantial decreases in median housing values, home equity, existing home sales, mortgage refinances, total housing starts and new home sales, and substantial increases in home mortgage delinquencies and foreclosures [13]. It is estimated that American homeowners have lost more than \$4 trillion in wealth associated with housing equity between July 2006 and July 2008 [14]. Foreclosures resulting from the housing market decline are associated with increased crime, decreased property values, and losses in tax revenues [15]. These negative impacts have been borne disproportionately by communities in the west, southeast, upper midwest, and portions of the northeast, by low- and middle-income households, and by black and Hispanic households [13]. The foreclosed housing crisis, combined along with longer-term adverse trends in rental housing, has resulted in increased pressure on the rental housing market and a mismatch between affordable rental housing supply and demand [16].

Public policy analysis and design can increase the efficiency of market-rate housing production. It can also reduce the magnitude of inequities within housing markets, as well as inequalities related to housing-related social outcomes. Management science and operations research, and related disciplines, can help determine when, where, what type and by what means affordable housing and sustainable communities might be built, redeveloped, and maintained. This article argues that decision modeling research that is interdisciplinary, that combines multiple analytical perspectives and that addresses the needs of multiple stakeholders and multiple policy objectives may provide useful guidance for policy analysis in housing and community development. Most of the policy motivation and definitions, and much of the

research described in this article, reflects a US perspective.

We review a number of key definitions used throughout this article. “Subsidized” and “assisted” housing refers to housing intended for low- and moderate-income families (in the United States, typically, those with incomes at or below 80% of the area median income) is produced with funds or incentives provided by federal, state or local governments. Means by which this is done for rental housing include government ownership and operation of newly built housing; government contracts or tax credits with private developers to produce housing, or direct subsidies to families to secure private-market housing on their own [17]. Owner-occupied housing can be produced using mortgage interest and real estate tax deductions, below-market interest rate mortgages, and mortgage insurance and support for government-sponsored enterprises that increase market demand for affordable housing financing instruments [4].

“Affordable” housing is targeted at middle- and lower-income families (typically, those with incomes at or below 120% of the area median income) and which does not consume more than 30% of a household’s income. Such housing, whether renter- or owner-occupied, may receive direct support from government sources, as for subsidized/assisted housing, or may be provided in exchange for economic incentives provided by political jurisdictions or entities responsible for them, or to conform with zoning rules [4]. “Workforce housing” is affordable housing intended specifically for households whose members provide essential municipal services [18].

Housing and communities can be built or modified to be economically, socially or environmentally “sustainable” [19]. For example, public policies or design standards may reduce the negative environmental impacts, such as energy consumption or pollution, of residential and community development [20]. Also, public policies or design standards may enable diverse families to live in housing and neighborhoods that allow broad access to economic and social mobility. Such communities may have the potential to smoothly

adapt to changes over time in employment, infrastructure, and demographics.

Decision models for housing and community development build on research and best practices in supply and demand analysis, land acquisition, construction, and management. However, these models, though numerous, diverse, and well-represented in high-quality scholarly research outlets, have not achieved their potential in policy and practice. Why, then, are they worth studying?

First, these are policy-relevant decision models. They address problems that affect choices or resources of individual families (“person-based” strategies) as well as problems that affect physical infrastructure or human resources of entire communities (“place-based” strategies) [21]. They address important policy and practice concerns such as minimizing costs, maximizing benefits, maximizing geographic deconcentration, and maximizing fair access to affordable housing and sustainable communities. Secondly, decision models may provide direct assistance to urban and regional planners who may rely on more traditional methods such as land-use zoning, subdivision regulation, growth management, smart growth, equitable development, and inclusionary zoning [22]. Finally, decision models may generate recommendations that balance national-level policy priorities, such as creating new housing choices, protecting current housing choices, and changing attitudes and preferences regarding housing choice [11].

Analysis of the research literature in decision models for housing and community development yields a number of insights. First, while long-lived, rich, and diverse, this literature is relatively thin and disconnected within the research community and disconnected from practice: innovative models and applications are published in diverse journals, often with nonoverlapping disciplinary audiences. Secondly, the lack of validation of decision models makes the research less attractive to policy-makers (who demand evidence that an innovative program is likely to improve outcomes) or to field managers (who seek guidance regarding routine scheduling and resource allocation decisions). Thirdly, the primary importance of these decision

models for practitioners is not their specific prescriptions or methodological innovations, but instead the potential for improved systems and process knowledge that makes better use of training and expertise. Finally, the current crisis in housing markets provides opportunities for novel applications for acquiring and redeveloping foreclosed housing units, designing more socially and economically sustainable housing construction and community development strategies, and enabling nonprofit housing providers to collaborate more effectively.

The remainder of this article is organized as follows: the first section is a review of the literature of decision modeling applications in housing and community development, with emphasis on those that address issues of affordability and sustainability. The next section synthesizes previous research and identifies key unanswered questions. This is followed by a section containing a research agenda for decision models in housing and community development; the last section concludes the article.

SURVEY OF DECISION MODELING APPLICATIONS

Our survey of decision modeling applications in affordable housing and sustainable community development is divided into three areas. *Descriptive* research seeks to explain what we observe; specifically, evidence regarding policy initiatives or strategies. *Prescriptive* research supports the identification of a most-preferred policy alternative or set of alternatives. *Decision support systems* (DSS) are information technology applications that automate the policy analysis and recommendation processes.

Descriptive Research

Descriptive research provides increased understanding of social phenomena that motivate or are influenced by policy initiatives. This research can identify the causes of specific events or observed outcomes, provide evidence regarding the efficacy of policy initiatives or social interventions, and can motivate and justify policy-relevant decision

models. Descriptive research for housing and community development encompasses disciplines within the social sciences (economics, policy analysis, urban and regional planning), engineering (civil engineering, industrial and systems engineering), as well as operations research and management science. The literature in these areas is vast, and we make no effort to provide a comprehensive review. In particular, we acknowledge that entire research journals and books are devoted to the study of housing, community development, urban economics, and urban affairs. The purpose of this brief review of a portion of this domain is to identify that subset of research which intends, or can be readily adapted, to support the design of prescriptive models for systems design/redesign. Nearly all of the research discussed in this section describes social phenomena in developed countries, especially the United States.

We distinguish between descriptive research that is *retrospective* (analysis of particular data sets, or literature reviews) and that which is *prospective* (systems models, sensitivity analyses, and simulations). Certain descriptive OR/MS models such as stochastic processes are, for the purposes of this article, classified as “prescriptive” because they are situated within a research tradition of analysis for system design/redesign.

Retrospective policy-analytic research, relevant to housing and community development, includes a historical survey of US low-income housing policy culminating in a proposal to fundamentally redesign housing policy to better meet the needs of low- and moderate-income families and communities [23], and a survey of current trends in transit-friendly, mixed-use development and redevelopment of distressed inner-city neighborhoods into mixed-income communities via public–private partnerships [24]. In addition, it is demonstrated in Ref. 25 that US consumers still overwhelmingly prefer the traditional suburban model of detached, single-family owner-occupied housing. A research review asserts that the presence of low- and moderate-income families in the low-density suburbs of Australia that

lack certain amenities, such as transit access, is not in itself evidence of “locational disadvantage” justifying social interventions; the role of individual social status and locational decisions balancing multiple criteria must be considered as well [26]. An examination of the Canadian rental housing sector since World War II [27] distinguishes markets for housing stock and for rental housing accommodations, describes trends in market outcomes, and identifies social policies that may have produced these outcomes.

There are many applications of housing construction engineering to increase affordability, energy efficiency, and structural integrity, as well as to decrease negative environmental impacts. Best practices are presented in Ref. 28 for increased use of alternative energy sources and more efficient heating and air conditioning systems. Advanced computer simulation methods and architectural methods to maximize passive solar exposure and minimize building footprints have resulted in significant potential energy savings [29]; similar technologies can be applied to rehabilitation of existing housing in low-income areas [30]. Process engineering methods such as concurrent engineering [31] and knowledge management [32] can increase the speed and quality of housing construction.

Descriptive models that are more prospective in nature can be classified according to the unit of observation and the level of aggregation. We consider first, those models that take a systems view, without explicit consideration of individual housing units or of individual households. A systems dynamics approach may be used to identify variables to measure environmental sustainability of different development strategies [33]. A critical review of conceptual models and planning frameworks for sustainable affordable housing results in a proposal of a new approach for affordable housing planning that addresses different development phases, is cross-disciplinary, and involves multiple experts and stakeholders [19]. Systems dynamics is used to model the social, economic, and environmental sustainability of housing and community development [34]. Alternative national-level

policies for renovation of the public housing stock are evaluated on the basis of empirically estimated survivor functions for housing estimated at the city level [35]. A proposed research agenda for social development—including housing—lies at the intersection of systems analysis, sustainable development, and MS/OR [36].

Another descriptive modeling approach addresses local, regional or national markets using housing units or households as the basis of analysis. Variations in economic relationships between private developers and public housing managers, and physical configurations of subsidized and market-rate housing are shown to have impacts on regional housing markets [37]. Analysis of production levels of social (subsidized) housing in Ontario is used to determine whether individual planning areas are receiving their “fair share” of social housing [38]. Housing mobility programs, which enable low-income families to choose housing in socially and economically diverse neighborhoods, may decrease regional-level well-being even if they achieve their programmatic goals [39]. Agent-based models may be used to simulate the spatial impacts of residential location on urban sprawl [40].

Other descriptive models use individual housing units, or families, as the unit of observation, and aggregate these actors to derive characteristics of larger systems. The relationship of an individual housing unit to its environment is used to define measures of environmental sustainability, and thus to measure sustainability impacts of housing-level performance targets [20]. Observations of individual housing units in a city are inputs to estimated survivor functions based on actuarial methods [41]. A life cycle analysis of housing using a stocks-and-flows-based model supports the evaluation of the benefits and costs of different housing construction and maintenance practices [42]. Observations of homes advertised for sale can help identify clusters of housing with shared attributes, as well as key physical determinants of housing choice [43]. Surveys and focus groups of residents in affordable housing are used to

build and validate a neural network model of residential satisfaction [44].

Much descriptive research that is relevant to decision models derived from observations of individual units and households, has a policy focus on affordable and assisted housing. A method for evaluating the benefits and costs of housing mobility programs is applied to early evaluations of a housing mobility experiment [45]. The American Housing Survey is used to estimate the likelihood of homeownership as a function of a variety of affordable lending policies [46] and to demonstrate that regulations that restrict the supply of newly constructed, market-rate housing can reduce the size of affordable housing stock [47].

Prescriptive Models

Prescriptive models for housing and community development can be classified as to their temporal and geographical scope, as well as programmatic and spatial specificity. Certain systems models abstract away the details of specific markets or population regions to concentrate on mathematical properties. A systems model of population that flows between living arrangements in the wake of a natural disaster is used to formulate multiple partial differential equations whose transient solutions allow evaluation of different public policies [48]. An optimal control model of a generic housing mobility initiative is used to identify stable and unstable long-term equilibria associated with different housing mobility policies [49,50].

Other models introduce limited spatial as well as programmatic specificity. Optimization of the social surplus associated with stylized land-use alternatives, subject to allocation and capacity constraints, yields insights regarding the influence of a parameter governing maximization of individual utility or of community utility [51].

Some prescriptive housing models are motivated directly by policy initiatives in defined geographic regions, but place less emphasis on specific spatial characteristics. Formula-based allocations and a gravity model are used to derive proposed allocations of affordable housing to portions of a metropolitan region [52]. A linear

programming model to allocate low-income households in defined zones in order to minimize total commuting and housing costs can contribute to the design and implementation of a fair housing policy [53]. Multiobjective math optimization is used to generate alternative potential allocations of households using rental vouchers to census tracts across a county that balances net social benefit and equity (see *Nonlinear Multiobjective Programming*) [54,55]; a variation of this model [56] incorporates uncertainty as to the actual locational outcomes of voucher recipients. A multiobjective model for location of project-based subsidized rental housing optimizes social efficiency and equity measures [57]; this model is extended to address affordable housing produced by governmental and nongovernmental organizations [58]. Production levels for affordable housing can be chosen to minimize total costs while accounting for environmental impacts and construction technology requirements [59].

Another stream of research develops regional planning strategies using detailed representations of programs and/or planning units. Urban renewal programs are designed based on the assignment of specific building types, levels, and prices to land parcels to optimize net social benefit [60]. A multiobjective land acquisition problem is solved on a grid to optimize compactness, acquisition, and development cost as well as land area [61], and proximity to high- and low-amenity communities and compactness [62]. A multicriteria planning problem for “smart growth” using actual, nonuniform land parcels and reflecting the perspectives of a government planner, an environmentalist, a conservationist, and a land developer yields a nonlinear integer multiobjective math program whose nondominated solutions provide specific guidance to diverse decision makers and stakeholders [63].

Tactical planning models for housing construction or redevelopment in specific, localized areas include Ref. 60, as well as other models where spatial concerns are less important. The Analytic Hierarchy Process is used to incorporate customer requirements for industrialized housing [31]. Math programs related to production scheduling

problems are used to design policies for relocating families in public housing communities undergoing renovations, to minimize total development time while ensuring that as few families as possible are displaced [64–66] (see the section titled “Single Machine Scheduling” in this encyclopedia).

Operational models for real estate practice are relatively rare. Multiattribute utility theory is used to rank applicants to a large commercial development; such a model could easily be applied to residential housing [67]. An application of queueing theory (see the section titled “The $M/M/1$ Queue” in this encyclopedia) evaluates the impacts of race-based versus non-race-based tenant assignment policies in public housing on levels of racial segregation and waiting times for available units [68].

Decision Support Systems

Research applications of DSS for housing and regional planning are numerous (see Ref. 69), but those focusing specifically on affordable housing and/or sustainable communities are less common. Computerized applications assist the US Army in forecasting demand and allocating resources for military housing [70,71]. Using an application for housing mobility planning [54] as the model engine, a spatial decision support system (SDSS) can provide strategic guidance to planners and counselors regarding housing mobility policy design [72]. A “proof-of-concept” DSS for individual housing mobility counselling is developed using the Analytic Hierarchy Process [73]; this work is extended in Ref. 74 to develop a Web-accessible prototype SDSS that reflects the needs of housing clients, counselors, and landlords. A spatial DSS supports property management and sales, as well as identification of potential properties for purchase [75].

SYNTHESIS OF PREVIOUS RESEARCH

There is a strong base of evidence from descriptive models upon which to develop prescriptive models and DSS for housing and community development planning, construction, and management. While there

is no single “canonical” prescriptive model that captures all elements of housing and community development, a generic multiobjective math programming model for this purpose might be presented as follows. Suppose $\mathbf{X}$ is a vector of decision variables that represent the location, type, and number of housing units to be built. Let $B(\mathbf{X})$ represent the net social benefit associated with housing provision strategy $\mathbf{X}$. $B(\cdot)$ can be nonlinear and capture impacts to residents of the housing under consideration, other community residents, and taxpayers. Let $E(\mathbf{X})$ represent the environmental impacts of housing provision strategy $\mathbf{X}$. Let $F(\mathbf{X})$ represent the perceived fairness, or equity, of the housing provision strategy. Then, a social planner would wish to solve

$$\text{Optimize } \{B(\mathbf{X}), E(\mathbf{X}), F(\mathbf{X})\}, \quad (1)$$

$$\text{s.t. } C(\mathbf{X}) \leq B, \quad (2)$$

$$D_{\text{Min}} \leq N(\mathbf{X}) \leq D_{\text{Max}}, \quad (3)$$

$$\mathbf{X} \in S, \quad (4)$$

where objective (1) balances social, environmental, and political considerations, constraint (2) ensures that development strategies obey resource limitations, and constraint (3) ensures that the level of housing provided lies within given estimates of minimum and maximum demand. Constraint (4) ensures that the decision variables obey all relevant spatial and programmatic constraints. This model could address policy design over multiple periods and incorporate uncertainty in housing markets. A large research literature addresses the solutions of models (1–4): well-known “classical” approaches include the weighting method and the constraint method [76]; more recent approaches include interactive methods, fuzzy optimization, and evolutionary algorithms [77] (see also *Nonlinear Multiobjective Programming*). Models such as 1–4 could be incorporated into SDSS.

As discussed above, other modeling approaches such as agent-based simulation, optimal control, and queueing theory could equally well generate alternative housing provision strategies. The practical utility of these planning models is a function of the

quality of evidence provided by descriptive research which generates insight into the social, environmental, and political impacts of housing and community development policies.

Research in housing and community development described in the previous section and summarized in model 1–4 above faces significant limitations. Prescriptive planning models which are partial-equilibrium, deterministic, and single-period in nature may be insufficiently flexible to address the diversity of problems typical of housing and community development. There does not appear to be a “theory” of affordable housing or sustainable community development that can be adapted to diverse regions, economies or housing types. There are few examples of explicit modeling of stakeholder values to generate decision models that achieve social goals shared across stakeholders (see the section titled “Basic Assumptions, Principles and Axioms of Normative Decision Analysis” in this encyclopedia). Few models attempt to jointly and explicitly address social welfare, equity (see *Fairness and Equity in Societal Decision Analysis*), and environmental impacts. There is little research on models linking strategic, tactical, and operational concerns that correspond to the process of policy planning, design, implementation, and evaluation, though Refs 47, 53, 70, and 72 address separately strategic, tactical, and operational aspects of housing mobility programs. With some exceptions [66,71], most models have neither been applied in the field nor rigorously evaluated according to best practices and specific real-world data.

These limitations motivate many questions that future research might address. Some of these include: How can descriptive models for policy analysis address multiple policy alternatives simultaneously? What types of prescriptive planning models are most appropriate for housing and community development? When are spatial versus non-spatial models most appropriate? What barriers prevent consistent use of prescriptive models? How can prescriptive models explicitly address the “geography of opportunity”?

How can speculative, forward-looking models be validated? How can modelers trade off model realism and detail against tractability?

RESEARCH AGENDA

We discuss a number of promising extensions to the decision modeling research described in this article.

Descriptive Models

It was argued above that a key element of prescriptive models for affordable housing and community development is the formulation and measurement of social welfare. Despite innovative models for measuring regional impacts of housing mobility programs that incorporate scale economies and variations across neighborhood types [39] and estimates of individual-level impacts of housing mobility programs [45], no similar work has addressed similar impacts associated with housing redevelopment programs. In addition, there is no research known to this author that evaluates the full range of social benefits and costs of housing and community development initiatives.

It would be of interest to formulate multistate dynamic models of affordable housing and community development programs that incorporate multiple transitions over space, class, and time associated with policy interventions such as particular assisted housing programs as well as normal class and household mobility; there has been initial limited effort in this area [78]. Another approach could extend current research on agent-based models for residential location, such as given in Ref. 40, to affordable housing and community development policy design. Here, agents could be individual families who participate in a housing mobility or housing redevelopment initiative.

The field of construction engineering and architecture can also benefit from research that applies current technologies to the design of sustainable housing units and communities. Agent-based modeling and cellular automata are applied to the design of virtual cities [79]. These designs are based on simulation models for energy-efficient

residential housing based on data from daily activities of residents [80].

Prescriptive Models

Housing providers and community development experts can choose from many affordable housing planning and management tools [81]. A multicriteria decision analysis could assist organizations in choosing the methods that are best-suited to their technical capabilities, funding streams, and service area characteristics. Another application might adapt methods from human-computer interaction research to evaluate the benefits perceived by housing and community development practitioners of decision models.

US Hurricanes Katrina and Rita in 2005, as well as the Indian Ocean earthquake/tsunami of 2004 are examples of natural disasters that can result in immense human and physical losses. While the urban planning profession has performed admirably in developing redevelopment strategies for New Orleans in the wake of Hurricane Katrina [82], there are opportunities for OR/MS to provide prescriptive planning models for urban redevelopment in the wake of natural disasters (see *Operations Research to Improve Disaster Supply Chain Management* and *Evacuation Planning*). Work by Jung *et al.* [83] is an initial effort in this direction, but much more research is needed.

Affordable housing providers face intense competition for increasingly limited development resources. A regional decision model could provide guidance regarding alternative strategies for collaboration across jurisdictional boundaries, service categories, and client populations.

Of great interest in the current foreclosure crisis is the development of strategies to select foreclosed housing units for purchase, redevelopment and resale, or ongoing management. A multiobjective discrete math programming model for strategy design in foreclosed housing acquisition is developed and applied to a small suburban municipality [84]. Current research extensions motivated by real-world practice include: selecting specific foreclosed housing units while addressing social benefits and costs,

alignment with strategic policy concerns; and extending the multiobjective acquisition model to incorporate uncertainty and risk.

Decision Support Systems

Information technology-enabled decision support is ubiquitous. However, practitioners in affordable housing and community development, especially those serving distressed communities, have limited access to IT applications that might help them make better decisions about the services to use, or provide a means for them to participate in the policy design. SDSS for affordable housing and community development could be developed so that they are easy for inexperienced users to master, use detailed housing market and community-level data, allow users to identify and rank decision alternatives with a variety of methods, and facilitate collaboration between multiple stakeholders. Preliminary analysis [85] has described the prospects of a professional-quality SDSS that might fulfill the promise of the prototype [74]. The application NEO CANDO ties together data from many different sources to support CDC investment decisions [86]. DSS might also be used to facilitate the design of energy-efficient residential units using engineering and architectural best practices. Finally, a recent graduate student service learning project has developed a DSS for management of services for the homeless [87, p. 3].

CONCLUSION

In this article, we have reviewed models for housing and community development, especially those that seek to address issues of affordability and sustainability. The research literature in this area is large, diverse, and long-lived but with substantial opportunities to perform research across disciplines, develop a general theory of prescriptive modeling and decision support, and generate real-world applications. A number of promising extensions may both, shed light on the dynamics of real-world behaviors of actors in the housing and community development process and provide

specific guidance to allow them to more fully enjoy the benefits of affordable housing and sustainable communities.

HYPER-HEURISTICS

GRAHAM KENDALL
EDMUND K. BURKE
University of Nottingham

INTRODUCTION

The purpose of this article is to present a brief overview of hyper-heuristics, which can be viewed as *heuristics to choose heuristics* [1] or as *heuristics to generate heuristics* [2]. This article provides an introduction to these two approaches, in addition to highlighting some of the relevant literature. For a comparison between meta-heuristics and hyper-heuristics, the reader is referred to Burke and Kendall [3], which provides tutorials on many common meta-heuristics as well as describing hyper-heuristics [4].

One of the key motivations of hyper-heuristic research is to raise the level of generality at which search algorithms operate, with a long-term research objective of being able to build search methodologies that are able to adapt themselves to different problem instances/domains with minimum human input. Figure 1 shows the current state of search methodologies, where the research effort with respect to hyper-heuristics is concentrated in the central position.

In addition, the study of hyper-heuristics raises a number of other research challenges. For example,

- To what extent can hyper-heuristic algorithms be self-tuning? One of the criticisms that could be levelled at some meta-heuristic approaches is that they require significant tuning for specific problem instance(s).
- Significant recent hyper-heuristic research has concentrated on *heuristics to choose heuristics*. While there are still many research directions to be investigated in this area, there is growing

interest in automating the process of creating or generating heuristics. This has received relatively little attention to date (but there has been a recent focus on using genetic programming to generate heuristics). This area is likely to become more important as it will enable users to utilise hyper-heuristics without having to implement a set of low-level heuristics.

- Hyper-heuristic research opens up the possibility of having an off the shelf system, which is able to address many different problem types, with minimal user intervention. A key research challenge that needs to be addressed to enable this type of system is how the problem can be represented.

As mentioned above, an important motivating goal of hyper-heuristic research is to raise the level of generality of search systems. However, it would be naïve to propose one general purpose search algorithm [5]. There is, nonetheless, significant scope to investigate more general search algorithms that are able to operate across a wider range of problems than is currently possible using bespoke algorithms, which are typically designed with a single-problem domain in mind, or even just a single-problem instance. Whilst there is much scientific merit in doing this, the algorithm is often only ever suitable for this domain and, possibly, just the particular benchmark instance(s) under consideration. Rather than attempting to get better and better solutions on a specific problem, one of the goals of hyper-heuristic research is to be able to get high-quality solutions across a range of problems, even if they are not as good as a bespoke algorithm on a single problem. Of course, we are still interested in finding solutions that are of as high a quality level as possible, recognising that if the main objective is to find the highest quality solution possible, for a given problem, then a bespoke algorithm is probably more appropriate. Therefore,

Figure 1. The drive toward more general search algorithms.

the goal is to build a methodology that can operate across different problem types without human recoding, redesign, or parameter setting. The solutions that are returned by a hyper-heuristic should, of course, be acceptable for an end user. However, the cost of producing the solution also needs to be acceptable as problem-specific approaches can be resource intensive (in terms of developmental time for other problems), especially if the software cannot be reused. A motivation of this research area is to recognise that this cost-quality trade-off underpins a series of key scientific challenges.

After briefly discussing the historical roots of hyper-heuristic research, we present the two major research directions that are currently being undertaken. The first, selects a heuristic from a supplied set to be applied to the current problem state. The second direction has the goal of generating heuristics. This is a less mature area, and we discuss the main research breakthroughs that have been made.

As hyper-heuristic algorithms are often implementations of meta-heuristics on heuristic search spaces we also provide

references to the relevant literature from this area.

There are several introductory chapters/papers which would be useful starting points for those new to the area [4,6–8].

HISTORICAL ROOTS

Although the term hyper-heuristics is relatively new, being first used in a published paper in 1997 [9], its roots can be traced back to the 1960s [10–12]. Work carried out more recently (but still not using the term hyper-heuristics) includes Dorndorf and Pesch [13], Hart [14,15], Schaffer and Eshelman [16], and Fang [17]. In Hart [14,15], for example, a two stage genetic algorithm [18] was employed. The genetic algorithm representation utilised both a direct and an indirect encoding, with the indirect encoding representing a sequence of heuristics in order to derive the schedule. This approach was shown to produce good quality solutions on a real-world scheduling problem, and was able to do so in a few minutes. Ross [19] studied a hyper-heuristic approach to the bin packing problem. Their hyper-heuristic was a Learning Classifier System [20]. Benchmark bin packing problems were initially solved using a set of heuristics taken from the literature. The learning classifier system was then used to find rules to associate each heuristic with the problem state, after which the problem state is consulted to decide which heuristic to apply next. This alters the problem state, so calling for another heuristic. When comparing the hyper-heuristic against using each heuristic in isolation, it was able to solve 78% of the benchmark problems to optimality and the best performing heuristic was only able to solve 73% to optimality. Bin packing was also the subject of Ross [1], with the hyper-heuristic now based on a genetic algorithm. The hyper-heuristic solved 80% of the benchmark datasets to optimality; slightly outperforming the learning classifier of Ross [19] and, again, producing superior results when using single heuristics in isolation. In Ross [21], a genetic algorithm based hyper-heuristic is utilised to construct

timetables for class and examination problems. The construction methodology does not involve any search or backtracking, and so the run time is predictable. The genetic algorithm searches over a set of heuristics, drawn from the literature, and decides which heuristic to invoke at each decision point. The results show that this hyper-heuristic performs well across a range of problem instances. Potvin [22] utilise a slightly different approach, to those described above, for vehicle routing problems. Their system, Micro-ALTO, supports algorithm designers via a graphical, interactive environment in order for them to specify problem solving strategies. We also note that adaptive algorithms have been in existence for some time. One well-known example is the adaptive strategy of Rechenberg [23], where control parameters were adjusted at run time. Although not a hyper-heuristic in the way that we have defined them, it does represent an algorithm that can adapt to its environment.

The first journal paper to use the term hyper-heuristic [24] investigated a tabu search based methodology across two different problems (university course timetabling and personnel rostering). The motivation for applying the methodology across two different domains was to test the hypothesis that the *same* algorithm is able to produce good results on two distinct problem types. The hyper-heuristic was based on tabu Search [25,26], together with a reinforcement learning [27] mechanism. The method performed well when compared against bespoke algorithms for these two problems.

HEURISTICS TO CHOOSE HEURISTICS

Many of the earlier hyper-heuristic approaches have a set of heuristics available that the hyper-heuristic is able to call upon, and the problem reduces to which heuristic to call at each decision point. In order to address the motivation of attempting to be as general as possible, a potential research direction is to build a hyper-heuristic approach which has no knowledge of the problem domain. In this situation, the hyper-heuristic only has a number of heuristics available and these can be called at any time. It only has to decide which heuristic to call. Figure 2 shows a suggested hyper-heuristic framework. At the top level, there is the hyper-heuristic domain. This is separated from the problem domain by a *domain barrier*. This restricts the hyper-heuristic from *knowing* anything about the domain on which it is operating, although there is no reason why we could not (or should not) *leak* some problem-specific information through this barrier with the goal of sacrificing *some* generality for *more* effectiveness. The implication is that we are able to switch the problem domain but still utilise the same hyper-heuristic algorithm while minimising other changes. That is, the *same* search algorithm can be used at the top level, with problem domain information being relegated to the lower level, so that it can be changed in order to address a different problem in the expectation that the hyper-heuristic will adapt itself to the new problem that has been presented.

Information that might be allowed to pass through the domain barrier could include

Figure 2. A hyper-heuristic framework.
Source: Adapted from Cowling *et al.* [28].

changes in the evaluation function, the execution time of a given heuristic, the past performance of each heuristic, and so on. The problem domain (lower level) of the framework consists of three distinct elements.

Set of Low-Level Heuristics

The heuristics that are provided as a part of the framework are typically drawn from existing heuristics in the literature. Typically, the framework is provided with as many heuristics as the researcher thinks are relevant, with a bias often being to provide too many, rather than too few. This bias is recommended because if a heuristic is not to be useful to the search, then an effective hyper-heuristic should adapt and not select that heuristic anyway.

By employing a standard template for each heuristic, the problem domain can be altered with no changes being required at the higher level of the framework.

One suggested, C++ style interface, is presented here

```
bool H1 (double & evaluation, int CPU time,
int iterations);
```

where

- The return value (Boolean) is true if the heuristic has modified the current solution in such a way that it satisfies all the hard constraints of the problem. That is, the current solution state represents a feasible solution. If the current solution is infeasible, then false is returned.
- The evaluation parameter is a reference parameter, so that the heuristic is able to return the evaluation of the current solution.
- The CPU time parameter specifies the amount of time the higher level strategy is allocating to H_n . Once that time limit has been exceeded, the heuristic must terminate and return a solution.
- The iterations parameter determines how many times the heuristic should be executed before returning.

Of course, this template is just one possibility. For example, the interface could

be modified so that it can search a search space which includes infeasible solutions which might be beneficial, if not essential, for some problems.

Representation of the Problem

Although the higher level hyper-heuristic often has no information about the problem on which it is operating, the framework must still represent the problem at the lower level. The most suitable representation can be derived from the scientific literature. The goal of developing representations which have some level of generality represents a major scientific challenge.

Evaluation Function

Utilising the framework shown in Fig. 2, various hyper-heuristics have been investigated. The following presents some of these research directions. It is not a comprehensive list, but a representative sample from recent work.

In Cowling [28] and Kendall [29], a *choice function* was used. This rates heuristic selection in three ways.

1. The performance of individual heuristics, rewarding heuristics which perform well and punishing poorly performing heuristics.
2. The performance of pairs of heuristics, on the basis that a heuristic may perform poorly but may be required in order to improve the performance of another heuristic.
3. How long is it since a heuristic has been called? This measure is a diversification strategy to ensure that a heuristic that has not been called for some time has the opportunity to be called again, even though it has not performed well in the past.

The choice function method was shown to be effective when applied to three different real-world problems.

A case-based heuristic selection method was investigated in Burke [30]. The paper is motivated by the idea of storing previously solved problems, together with the heuristics that were used on that problem. When

presented with a new problem, a similar problem is found in the case-base and the same heuristics are utilised.

The focus of the work in Bai [31] is shelf-space allocation within supermarkets. It utilises a variety of methodologies, including greedy heuristics, GRASP (greedy randomised adaptive search procedure) [32], and simulated annealing [33], to produce results against which the hyper-heuristic is compared against. The major contribution of Bai [31] is the presentation of three different hyper-heuristics, a tabu search based hyper-heuristic based on Burke [24], a simulated annealing hyper-heuristic that was proposed in Bai and Kendall [34], and a hybridisation of these two hyper-heuristics. All the three hyper-heuristics use the same set of low-level heuristics, which comprised four types of n -opt exchange operators. The results demonstrate that the hyper-heuristic approaches produced the same results, or were superior to the other methods presented in the paper.

There have been a number of studies which have utilised tabu search as a hyper-heuristic. One tabu search approach [1] has been discussed above (see the section titled “Introduction”), but other papers [35,36] also draw on the idea that certain heuristics should be made *tabu* at a given time in order to stop them being called.

Other hyper-heuristic approaches include those based on genetic algorithms [37], graphs [38,39], and simulated annealing [40].

HEURISTICS TO GENERATE HEURISTICS

One of the criticisms that can be levelled at approaches which are based around *heuristics to choose heuristics* is that for each problem domain, the researcher (or user) has to define and implement a new set of low-level heuristics. This is not only time consuming but it also often requires knowledge of the area and the ability to access and interpret the scientific literature.

In order to address this issue, there has been some work recently on automatically generating heuristics. There are at least two motivations for doing this.

1. If we are presented with a problem that does not have a suitable heuristic available (or we do not have the time/money to develop a suitable heuristic ourselves), we may be able to automatically generate a heuristic that is able to produce a good quality solution to the problem at hand.
2. We may be able to automatically build new, perhaps unintuitive, heuristics that we can use as our set of low-level heuristics.

The work we discuss in this section starts to address point 1. The research for point 2 is still in its very early stages.

The approach described in Burke and Newall [41] generated heuristic orderings for examination timetabling, which can be viewed as finding new heuristics. The approach drew upon the squeaky wheel optimisation method [42] and was applied to examination timetabling. The work is motivated by the following observations. When scheduling examinations, a common method is to sort the examinations into some order (representing a view of what is most difficult), and then schedule the examinations in the order they appear in the list. The approach in Burke and Newall [41] considers a heuristic as being such an ordering. It uses human designed heuristics as a starting point, and looks at those exams which cause the highest penalty and promotes them up the order. At the end of the algorithm, a new heuristic (ordering) has been generated. In Burke and Newall [41], this was referred to as an *adaptive* heuristic. The method was shown to be effective on a range of benchmarks instances.

Another research initiative for generating heuristics is based on Genetic Programming [43], applied to n -dimensional packing problems [44]. In this approach [2], genetic programming is utilised to evolve a function that determines into which bin to place a given piece. This is done by placing an item into a bin and using this problem state as input to the genetic programming function. The function is applied to all item/bin pairs, and the item/pair which returns the maximal value is the placement that is used. The approach is competitive with human designed heuristics

but has also been developed to operate across different dimensions of the problem (one-, two-, and three-dimensional), where only the problem domain changes and the hyper-heuristic remains constant.

CONCLUSIONS

We have presented a very brief introduction and overview of hyper-heuristics, including references to some of the historical work which did not use the term, but which can be recognised as representing the scientific roots of the area.

The article has focussed on two types of hyper-heuristics [6]. *Heuristics to choose heuristics* select the next heuristic to apply from a given set of (usually) human designed heuristics. As one of the key aims of this methodology is to raise the level of generality, the hyper-heuristic algorithm is often separated from the low-level heuristics, and the evaluation function, so that we can switch the low-level heuristics and so address a different problem domain.

An emerging research direction is represented by *heuristics to generate heuristics*. To date there has been limited work in this area, mainly focusing on evolving heuristics using genetic programming. The aim of this approach is to generate heuristics which a human could not (or would not have the time/resources) design.

Although hyper-heuristics have their roots in the 1960s, they have only recently started to receive significant research interest. We hope that this article has provided the reader with a starting point on which to increase their knowledge and understanding of hyper-heuristics and that it enables other researchers to make a contribution to this still emerging area.

ICE HOCKEY

ARMANN INGOLFSSON
School of Business,
University of Alberta,
Edmonton, Alberta,
Canada

Ice hockey is a popular team sport, particularly in cold climates such as in Canada, the northern part of the United States, Russia, and northern Europe. The primary professional ice hockey league is the National Hockey League (NHL), which operates in the United States and Canada and draws players from throughout the world. As it is the case with *baseball*, *football* (see ***American Football: Rules and Research***), *soccer* (see ***Soccer/World Football***), and *basketball*, various operations research (OR) methods and statistical analyses have been used to address questions of interest to ice hockey fans, coaches, and managers. This article outlines published work on such questions and elaborates on two issues: (i) determining the optimal time to “pull the goalie” near the end of an ice hockey game and (ii) estimating the probability that a team will qualify for the NHL playoffs. Rules vary among ice hockey leagues, but all the descriptions and empirical results described in this article refer to the NHL, unless otherwise noted.

An ice hockey team normally has six players on the ice during a game: a goaltender (“goalie”), two defensemen, and three forwards (center, right wing, and left wing). Players rotate onto the ice in shifts of about 1 min. The players use sticks to propel the “puck” (a black rubber disc), with the aim of scoring goals by shooting the puck into the opposing team’s goal. Penalties to players for rule infractions are common (an average 2007–2008 NHL game had 27.3 penalty minutes), resulting in the penalized team playing “shorthanded”; the opposing team is said to be on the “power play.” A game lasts for 60 min, comprising three 20-min periods. During the NHL’s regular season

of 82 games for each team, if the score is tied after three periods (so-called “regulation time”), the teams play one overtime period that lasts for 5 min or until one of the teams scores. If the score remains tied after the 5-min overtime period, the game outcome is determined by a “shootout,” during which a chosen set of players from the two teams alternate in taking penalty shots (where a single skater attempts to score on an undefended goalie). The overtime rules change during the NHL playoffs in that overtime continues, in 20-min periods, until one team scores a goal. During the regular season, a win is worth two points and an overtime loss is worth one point in the standings. A loss during regulation time is worth no points.

The NHL has 30 teams, divided into two 15-team Conferences, each of which is subdivided into three five-team Divisions. The top eight teams from each Conference advance to the playoffs, in which pairs of teams play a series of a maximum of seven games, with the first team to win four games advancing to the next round of the playoffs. The top team from each Conference plays in the final series, and the winning team is awarded the Stanley Cup.

Researchers from various fields, including OR, statistics, economics, and management strategy, have developed mathematical models of ice hockey. Although I focus on OR models, I touch on contributions from these other fields. The interplay between statistical analysis and decision modeling is important. For example, the utility of models to choose an optimal player order for a shootout [e.g., Ref. 1] depends on how precisely the shootout scoring probabilities of different players are known.

POISSON GOAL SCORING PROCESSES

Perhaps the most important and useful modeling device for understanding the dynamics of hockey games is the assumption that scoring follows a *Poisson process* (see ***Poisson Process and its Generalizations***), an

assumption that can be justified by taking a first-principles approach. Call the teams in a hockey game A and B and imagine dividing the 60 min of regulation play into intervals of, say, $\Delta t = 30$ s. Assume that during each interval, Team A scores with probability $\alpha \Delta t$ and does not score with probability $1 - \alpha \Delta t$, independent of scoring in other intervals and independent of whether or not Team B scores in the interval. The parameter α is Team A's goal-scoring rate. Given these assumptions, N_A , the number of goals that Team A scores in the game, will follow a binomial distribution with mean αT , where T is the length of the game. Letting Δt approach zero, the binomial distribution approaches a Poisson distribution with mean αT [e.g., (2, Section 5.2)]. A symmetric set of assumptions for Team B implies that its scoring will follow a Poisson process with rate β , which implies that, N_B , the number of goals that Team B scores in the game, has a Poisson distribution with rate βT . Thus, we have reduced the dynamics of the game to two independent and competing Poisson processes.

Before scrutinizing the validity of the assumptions that led to the Poisson processes, I illustrate their usefulness by demonstrating how one can compute the probability that Team A wins the game during "regular time," that is, before overtime. (Ref. 3 describes an alternative approach, based on the same assumptions.) Starting from the law of total probability and the property that the superposition of two independent Poisson processes is a Poisson process, we see that

$$\begin{aligned} \Pr\{A \text{ wins}\} &= \Pr\{N_A > N_B\} \\ &= \sum_{n=1}^{\infty} \Pr\{N_A > N_B \mid N_A + N_B = n\} \\ &\quad \times \frac{((\alpha + \beta)T)^n e^{-(\alpha + \beta)T}}{n!}. \end{aligned} \quad (1)$$

Now, let us view N_A as being obtained from $N_A + N_B$ by thinning; that is, whenever a goal is scored, Team A scored the goal with probability $p = \alpha/(\alpha + \beta)$, independent of all other goals. This implies that if the total number of goals in the game

is n , then the number of goals scored by Team A follows a binomial distribution with parameters n and p . Therefore, the term $\Pr\{N_A > N_B \mid N_A + N_B = n\}$ equals the probability that a binomial random variable with parameters n and p is larger than $n/2$, which is easily calculated. We approximate the infinite series in Equation (1) with the sum of the first m terms. The resulting truncation error is bounded by $\sum_{n=m+1}^{\infty} ((\alpha + \beta)T)^n \exp(-(\alpha + \beta)T)/n!$ —that is, by the complementary distribution function for a Poisson random variable with mean $(\alpha + \beta)T$. To estimate how many terms are needed for an accurate approximation, suppose that $(\alpha + \beta)T$, which is the average number of goals per game, equals 6 (which is roughly consistent with the last few NHL seasons). With this goals-per-game average, truncating the infinite series after 20 terms results in a truncation error of about 10^{-6} .

Near the end of the NHL's 2008–2009 regular season, the Detroit Red Wings were the top scoring team, with a goal scoring average of 3.63 per game, followed by the Boston Bruins, with an average of 3.28 per game. The lowest scoring team, the Phoenix Coyotes, averaged 2.43 goals per game. The calculation I have outlined results in the Red Wings having a 0.48 probability of winning a game against the Bruins in regular time (with a 0.37 probability of a loss and 0.15 probability of a tie) and a 0.61 probability of winning a game against the Coyotes in regular time (with a 0.24 probability of a loss and 0.15 probability of a tie). Table 1 illustrates the calculation for the Red Wings versus the Bruins. To refine this analysis, instead of using average goal-scoring rates against all teams, one could attempt to classify teams based on ability and estimate average goal-scoring rates for each team as a function of the opposing team's ability.

Let us now revisit the assumptions that led us to model scoring by Teams A and B as independent Poisson processes. References 3 and 4 demonstrate empirically that the Poisson approximation is fairly accurate. Two assumptions are particularly suspect, if taken literally. First, there are various reasons to expect that the goal-scoring rate of

Table 1. Calculation of the Probability that the Detroit Red Wings Win in Regular Time, if Playing the Boston Bruins

Number of Goals (n)	$\Pr\{n \text{ Goals}\}$	Number of Goals Needed to Win	$\Pr\{\text{Red Wings Win}\}$
1	0.015	1	0.525
2	0.045	2	0.276
3	0.089	2	0.538
4	0.134	3	0.351
5	0.161	3	0.547
—	—	—	—
20	3.7×10^{-6}	11	0.503
$\Pr\{\text{Red Wings win}\} = 0.48$		Error bound: 1.2×10^{-5}	

one team may depend on the goal-scoring rate of the other team. For example, one could expect that if Team A scores the first goal, then Team B will respond by “trying harder” and its goal-scoring rate will increase. Such hypotheses say nothing, however, about whether or not the dependence between the two processes is large enough to cause concern. This approximation appears to be defensible, as the only study that, to my knowledge, has investigated this issue [3] found no statistical evidence against the independence assumption. Secondly, one would expect that a certain minimum time must elapse between one goal and the next, thus violating the assumption that the probability of a goal in the next infinitesimal interval does not depend on when the last goal was scored. Reference 5 investigated this issue in detail, and found that a generalization of the Poisson process, whereby the goal-scoring rate increases gradually from zero to a constant rate as time from the last goal increases and provides a good fit to empirical data on the times at which goals were scored in the NHL. Based on the analysis in Ref. 5, the “warm-up” time required before the goal-scoring rate reaches the constant value appears to be approximately 20 s. Although the model in Ref. 5 is undoubtedly more realistic, the Poisson model provides a reasonable and relatively tractable first approximation to the dynamics of a hockey game.

Goal scoring by individual players has also been modeled as a Poisson process. For example, Refs 6 and 7 demonstrate that the distribution of the number of points (goals plus assists) per game for former

NHL player Wayne Gretzky—the “Great One”—is remarkably well approximated by a Poisson distribution, with a mean of 2.39 points per game.

The frequency of “hat tricks” (a player scoring three or more goals in a game) is another measure that can be understood in terms of a Poisson process model. In the fall of 2008, Teemu Selanne scored his twenty-first career hat trick. This was described as a “statistical oddity” [8] by one sports writer, because Selanne has scored more hat tricks in 16 seasons than Gordie Howe, the NHL’s most durable player, had scored in 26 seasons, while scoring fewer total goals than Howe did. Is Selanne’s achievement unusual, from a statistical point of view? Let us use the Poisson model and try to answer that question. At the time, Selanne had played 1080 regular season NHL games and had scored 560 goals, for a 0.52 goals-per-game average. If Selanne’s goal production follows a Poisson process with a constant rate of 0.52 goals per game, then we can compute the probability that he scores zero goals ($\exp(-0.52) = 0.60$), one goal ($0.52 \exp(-0.52) = 0.31$), two goals ($0.52^2 \exp(-0.52)/2 = 0.08$), or three or more goals ($1 - 0.60 - 0.31 - 0.08 = 0.016$) in a game. Using the 0.016 estimate of Selanne’s hat trick probability, we can estimate an expected number of hat tricks for him to be $1080 \times 0.016 = 17.10$. Because a Poisson distribution’s variance equals the mean, the standard deviation equals $\sqrt{17.10} = 4.13$; if the Poisson model is accurate, therefore, we would expect Selanne’s actual number of hat tricks (21) to have a 68% probability (based

on a normal distribution approximation) of falling within 17.10 ± 4.13 , as indeed it does, albeit at the high end of the range. From this perspective, Selanne's achievement is close to what one would expect, given his total number of games played and total number of goals scored. If one does the same analysis for Howe, one obtains an expected value of 19.60 total hat tricks with a standard deviation of 4.43. Howe's actual number of hat tricks was 19—very close to the expected value. Thus, the reasoning that players with a higher total number of goals and higher total number of seasons are likely to have a higher total number of hat tricks is false. In order to be likely to score hat tricks, a player must have a high goals-per-game average, and this matters more than the total number of goals.

If one repeats the hat trick analysis for several other players who were mentioned in Ref. 8, two stand out as having had a significantly greater number of hat tricks than expected: Wayne Gretzky (50 actual, 34.55 expected) and Glenn Anderson (21 actual, 11.64 expected). The players mentioned in Ref. 8 are primarily ones that are at the top of the list of hat trick scorers, so these players do not constitute a random sample of NHL players. For that reason alone, one would expect the number of hat tricks for this group of players to be biased upwards, a point on which Ref. 9 elaborates. However, there are other factors involved. Let us take a closer look at Gretzky. His expected number of hat tricks is 34.55 but he actually had 50 hat tricks, which is well outside the standard deviation of 5.88. One of many unusual things about Gretzky is how much his goals-per-game average changed during his career, from 1.15 in the 1981–1982 season to 0.13 in the 1999–2000 season. Computing the expected number of hat tricks separately for every season (which corresponds to assuming that Gretzky's goal-scoring process was a Poisson process with a time-varying rate) should result in a better estimate. Adding the expected number of hat tricks for each season results in an expected value of 47.6 career hat tricks, with a standard deviation of 6.91. With this approach, Gretzky's 50 actual

career hat tricks are well within one standard deviation of the expected value.

EMPIRICAL EVIDENCE ABOUT ICE HOCKEY

A number of other questions about ice hockey have been investigated empirically, including the following:

- Can a team's win/loss percentage be predicted from the number of goals, for (GF) and against (GA)? Baseball statistician Bill James [10] found that for major league baseball, teams' win/loss percentages were well approximated by $(\text{runs scored})^2 / [(\text{runs scored})^2 + (\text{runs allowed})^2]$ and he referred to this as the Pythagorean method. In an attempt to develop a similar formula for ice hockey, Cochran and Blackstock [11] found that NHL teams' regulation time win/loss percentages over a season (adjusted for ties) were well approximated by $\text{GF}^{1.927} / (\text{GF}^{1.927} + \text{GA}^{1.927})$.
- How likely is a player to score on a penalty shot during a shootout? According to Ref. 12, the overall average scoring probability is 0.33. The probability is only slightly higher (0.34) for the first six shooters (who were presumably chosen for their scoring ability) than the later shooters (0.31). According to the same reference, scoring probabilities differ only marginally, depending on the importance of the shot ("must make" vs. "could win" vs. "no pressure").
- The longest shootout in NHL history involved 30 shooters, in a 2005 game between the New York Rangers and the Washington Capitals. How long will we have to wait for a 40-shooter shootout? According to estimates in Ref. 12, 40-shooter shootouts can be expected to occur once every 156 seasons, on average.
- More than half the regular season games that reach overtime remain tied at the end of overtime and are therefore determined by a shootout. Is the overtime period too short? According

to estimates in Ref. 13, if the overtime period were extended from 5 to 10 min, then the fraction of overtime games that are decided by a shootout would drop from 0.53 to 0.28.

- If a team is leading after two periods, how likely is it that it will win the game? According to Ref. 4, the answer is 0.72 if the team is playing at home and is leading by one goal, 0.92 if it is leading by two goals, and 0.98 if leading by three goals. The probabilities are slightly lower for teams playing away from home.
- A related question is “when is a goal most valuable?” Or, in other words, under what circumstances is goal scoring most likely to increase the probability of winning the game? According to Ref. 5, not surprisingly, a goal is most valuable if the score is close to being tied and little time is left in the game. As an example, Ref. 5 estimates that a game-tying goal with 5 min remaining in regulation time increases the probability of winning the game for the scoring team from 0.10 to 0.40.
- Are referees biased, or as Ref. 14 puts the opposite possibility, are referees Markov (i.e., “memoryless”)? These authors find that the home team receives fewer penalties on average, a finding that is consistent with similar analyses for soccer. (Instead of referee bias, a possible alternative explanation that has not been investigated to my knowledge, is that the home team commits fewer penalties, on average.) A second type of bias that Ref. 14 investigated is “follow-up bias”, in which a referee that penalized Team A last is more likely to penalize Team B next. According to estimates in Ref. 14, if the home team gets the first penalty, the probability that the away team gets the second penalty is 0.62. If the home team receives the first two penalties, the probability that the away team gets the third penalty is 0.65.
- If Wayne Gretzky and Mario Lemieux had reached their peak in the same year, and played on equally strong teams, who would have scored more points? Reference 7 develops a “statistical time machine” to answer such questions and it gives the edge to Lemieux.
- Is the “hot goalie” a myth, as Ref. 15 argues is the case for the “hot hand” in basketball? Reference 16 examines the performance of the Detroit Red Wings in their four-game sweep of the Stanley Cup final series in 1997, with Mike Vernon in goal, and concludes that the “hot goalie hypothesis is alive and well.”
- When a team performs poorly, a typical reaction is to fire the coach. Does firing the coach work? Management strategists have investigated team leadership in the context of NHL hockey, particularly for coach succession. According to Refs 17 and 18, when a coaching change occurs between seasons, the team’s performance remains about the same, on average. When a coach is replaced during a season, the team performance worsens, on average, during the remainder of the season. If a coach taking over during a season continues to coach in the following season, the team’s performance improves, on average during the second season. The explanation offered by Ref. 17 is that a coaching change during the season gives the new coach an opportunity to evaluate players, make roster changes, and influence player training during the offseason, all of which result in improved performance during the next season.
- Does awarding one point for an overtime loss cause teams to play more defensively if they are tied near the end of regulation time? A series of articles by economists on this topic [19–22] uses models of goal scoring (similar to our Poisson process assumptions) and empirical data to suggest that the answer is yes, and that this phenomenon has increased the frequency of overtime games.
- What determines player salaries? There is a sizable literature in sports

economics (see Ref. 23 for a review) that attempts to relate player salaries to such factors as market structure, nationality, and player type. For example, Ref. 24 found that NHL players from Sweden and Finland were higher-paid, on average, than players from Canada, the United States, Russia, and the former Czechoslovakia, perhaps because Swedish and Finnish players have relatively more attractive options for playing in their home countries rather than the NHL. As another example, after the short-lived World Hockey Association (WHA; an NHL competitor) folded, Jones and Walsh [25] estimated NHL players' contribution to team revenue and compared them to players' salaries. They found that, on average, player salaries exceeded their contribution to team revenue—a result that is consistent with the NHL having increased player salaries beyond the point of profitability, in order to drive the WHA out of business.

WHEN TO PULL THE GOALIE

Moving on to decision models, operations researchers have studied one decision particularly intensely: When should a coach “pull the goalie?” If a hockey team is down by one goal near the end of a game, the coach will often replace the goalie with another player, so that the team has six skating players against the opponent's five. Pulling the goalie increases the team's goal-scoring rate, thus increasing the probability that the team will tie the game. The opponent's goal-scoring rate is likely to increase even more, thus increasing the probability that the team loses by more than one goal, but in terms of points in the standings, a loss is worth zero points, regardless of how many goals separate the teams. (Although goal differential could matter at the end of the season, as it is used as a tiebreaker in determining which teams enter the playoffs.) Therefore, when the probability of a win is close to zero, a strategy that increases the probability of

a tie and thus entering overtime is worthwhile, even if the strategy also increases the probability of losing by a larger margin.

How do NHL coaches decide when to pull the goalie? Former Los Angeles Kings head coach, Andy Murray, was quoted in 1994 [26] as saying “if you're down by one goal, you're looking at the 1 min mark.” The “one minute when trailing by one” rule is also mentioned in Refs 27–31, all of whom analyze the decision mathematically and conclude that it would be better to pull the goalie more than 1 min before the end of the game. Recall our assumption that scoring by the two teams can be modeled as independent Poisson processes with rates α and β . If Team A pulls its goalie, suppose that its goal-scoring rate increases from α to α' and Team B's goal-scoring rate increases from β to β' , and further assume that $\beta' > \alpha'$. With T min remaining in the game and Team A trailing by one goal, suppose that Team A decides to pull its goalie when $t < T$ min are left, if it is still trailing by one goal at that point. This strategy will result in a tie if Team A scores the next goal. Following Refs 28–30, I computed the probability that Team A scores the next goal separately for two cases: (i) the next goal is scored in the interval from T to t min and (ii) the next goal is scored in the last t min. Under case (i), Team A scores the next goal if the following two events occur:

- The teams score at least one goal in the interval from T to t (with probability $1 - \exp(-(\alpha + \beta)(T - t))$).
- Conditional on the preceding event, Team A scores the first goal (with probability $\alpha/(\alpha + \beta)$).

Under case (ii), Team A scores the next goal if the following three events occur:

- Neither team scores in the interval from T to t min (with probability $\exp(-(\alpha + \beta)(T - t))$).
- The teams score at least one goal in the last t min (with probability $1 - \exp(-(\alpha' + \beta')t)$).
- Conditional on the preceding event, Team A scores the first goal (with probability $\alpha'/(\alpha' + \beta')$).

By combining terms, we obtain the probability that Team A obtains a tie sometime before the game ends, as a function of T and t :

$$f(T, t) = (1 - e^{-(\alpha+\beta)(T-t)}) \frac{\alpha}{\alpha + \beta} + e^{-(\alpha+\beta)(T-t)} (1 - e^{-(\alpha'+\beta')t}) \frac{\alpha'}{\alpha' + \beta'} \quad (2)$$

One obtains the optimal time to pull the goalie by maximizing f with respect to t . One can find the optimal time t^* analytically [28] and t^* has the desirable property that it does not depend on T , but it is perhaps more insightful to plot how f depends on t for a given T . As an example, suppose that in a game between the Red Wings and the Coyotes, the Red Wings are trailing by one goal with $T = 5$ min remaining. Figure 1 shows how the probability that the Red Wings will tie the game before it ends (i.e., $f(5, t)$) depends on the time t at which the Red Wings coach pulls the goalie, if the Red Wings have not tied it already. The probability of a tie is computed using Equation (2) and the goal-scoring rate estimates discussed earlier. Pulling the goalie with 1 min remaining results in a tie probability of 0.279. The optimal time to pull the goalie is considerably earlier than 1 min before the end of the game: approximately 2.5 min. By pulling the goalie earlier, the probability of a tie increases from 0.279 to 0.295.

The models and the goal-scoring rate estimates in Refs 27–31 differ, but all of these

papers reach the same conclusion: it is optimal to pull the goalie with more than one min remaining (the estimates of t^* in these papers range from 1.3 to 4 min). As one would expect, strong teams (with high α) should pull their goalie sooner than weak teams do, and teams playing against a strong opponent (with high β) should pull their goalie later than should teams playing a weak opponent [29].

WILL MY TEAM QUALIFY FOR THE PLAYOFFS?

As of 20 March 2009, the Edmonton Oilers had played 70 of their 82 regular season games and had earned 77 points, putting them in seventh place in the NHL's Western Conference. As is usually the case at this time of the year, for me and other Oilers fans there was considerable uncertainty about whether or not the Oilers would be one of the eight Western Conference teams to earn a playoff spot. *Simulation* and *optimization* can provide different and complementary answers to this question. Optimization [e.g., [32,33]] can sometimes provide a definite “yes” or “no” answer, whereas simulation [34] can provide an estimate of the probability that the answer will be “yes.” Simulation can also provide additional information—about how many points will most likely be needed to qualify for the playoffs, for example, or the probability that a team will qualify, given that it earns X points in its last Y games.

I now describe the Monte Carlo simulation model in Ref. 34 in greater detail. The web

Figure 1. Probability of a tie as a function of the time the goalie is pulled.

site <http://www.sportsclubstats.com/NHL.html> shows the results of a similar simulation model. The building block of the model is the simulation of the outcome of every remaining regular season game. To simulate the outcome of a game between Teams A and B, one requires as input the probability that Team A will win the game. A simple approach, adopted in Ref. 34, is to use the average of Team A's winning percentage and Team B's losing percentage at that point in the season (Ref. 34 provides additional details, including how to simulate overtime games). Alternatively, one could use the approach described at the beginning of this article, an approach that involves computing win probabilities based on the team's goal-scoring rates and Poisson assumptions. Another option is a statistical model that estimates win probabilities by incorporating such factors as home-ice advantage, offensive capability, defensive capability, and player injuries.

In each replication of the simulation, one simulates every remaining regular season game. Then, one computes the simulated standings at the end of the season, according to the NHL's ranking criteria, which are the following, in decreasing order of priority:

- Top ranking within a Division guarantees a top three standing in the Conference;
- Total points;
- Total wins;
- Results of head-to-head games for teams that are tied based on the first three criteria;
- Total goals for (GF) minus total goals against (GA).

Interestingly, before 1970, the NHL used GF instead of GF–GA as the final criterion; as discussed in Ref. 35, this led to perverse incentives near the end of the 1969–1970 regular season. In the Montreal Canadiens' final game that season, trailing 5–2 against the Chicago Blackhawks, the Canadiens could have qualified for the playoffs if they had scored three more goals, regardless of how many more goals the Blackhawks

scored. The Canadiens followed the rational strategy, given the ranking criteria, of pulling their goalie at the beginning of the third period—but without success. Reference 35 uses regression analysis to argue that GF–GA is a better tie breaker, and the NHL has since adopted this approach.

Simulation has an advantage over optimization in handling arbitrarily complex ranking criteria. The approach used in Ref. 34 is to rank teams based on “pseudo points,” computed as follows:

$$\text{Pseudo points} = M(1) \times (\text{Criterion 1}) + \dots + M(n) \times (\text{Criterion } n), \quad (3)$$

where $M(1) \gg \dots \gg M(n) > 0$, in order to enforce the strict prioritization of the factors. Put differently, the teams are ordered lexicographically, based on the ranking criteria. If some of the criteria are difficult to implement in the simulation model (e.g., the results of head-to-head games) and are unlikely to make a difference, then one can either ignore them (and eliminate replications where those criteria made a difference) or replace those criteria with a random number in order to break ties that remain after applying the criteria that are explicitly included in the simulation.

Table 2 shows an example of simulation results for the NHL's Western Conference, as of 19 March 2009 and based on 5000 replications, focusing on the Edmonton Oilers. Each row in the table corresponds to one replication. On the basis of these replications, one can estimate the probability that the Oilers qualify for the playoffs (0.624) and the average number of points needed to qualify (88.9), by computing simple averages.

I show two examples to illustrate how one can dig deeper into the simulation results to answer interesting questions. First, how does the probability that the Oilers qualify for the playoffs depend on the number of points they earn from their remaining 12 games? Table 3 shows a cross-tabulation obtained from the simulation results and it answers this question (there were no replications in which the Oilers earned 0, 23, or 24 points in their final 12 games). If Edmonton were to earn 12 of the 24 available remaining points,

Table 2. NHL Western Conference Simulation Results, as of 19 March 2009

Replication	Edm. Rank	Edm. Points	Edm. Qualifies?	Points Needed to Qualify
1	6	94	Yes	92
2	11	86	No	*
3	10	86	No	87
—	—	—	—	—
5 000	5	95	Yes	89

*Simulated criteria insufficient to determine top 8 teams

their probability of qualifying would be 0.73; to bring the probability to 0.99, they would need to earn 14 of the 24 available points.

Secondly, sports writers sometimes use a two-step process to estimate how many points a team will need to achieve to qualify for the playoffs: (i) estimate the number of points X that will be needed to qualify and (ii) subtract the team's current number of points from X . Implicit in this approach is an assumption that the random variable X is independent of whether or not the team of interest qualifies. Put in more concrete terms, the question is whether the distribution of the minimum number of points needed to qualify for the playoffs depends on whether the Edmonton Oilers qualify. By cross-tabulating the simulated values of X against an indicator variable for whether or not Edmonton qualifies, one can produce a graph like the one shown in Fig. 2. As that figure shows, more points are needed to qualify, on average, if Edmonton qualifies than if it does not. To understand this outcome, keep in mind that

Table 3. Cross-tabulation of Edmonton Oilers Points and Whether Edmonton Qualifies for the Playoffs

Pts. in Last 12 Games	Edm. does not Qualify	Edm. Qualifies	Pr (Edm. Qualifies)
1	1		
2	4		
3	6		
4	22		
5	37		
6	86		
7	152		
8	278	2	0.01
9	315	17	0.05
10	404	115	0.22
11	327	207	0.39
12	173	469	0.73
13	66	537	0.89
14	8	583	0.99
15	2	416	1.00
16		316	1.00
17		206	1.00
18		143	1.00
19		55	1.00
20		37	1.00
21		11	1.00
22		5	1.00
Totals	1881	3119	

in the current standings, Edmonton is in the top 8. If Edmonton ends up not qualifying, it means that the Oilers performed relatively poorly during the remainder of the season, which would tend to reduce the qualification threshold for teams that are below the Oilers in the current standings.

**Figure 2.** Distribution of number of points needed to qualify, depending on whether Edmonton qualifies.

In conclusion, operations research and statistical analyzes can provide insight and predictions about game strategies, whether a team will make the playoffs, the consequences of rule changes, and a variety of other issues of interest to ice hockey sportswriters, analysts, and fans. I hope that this article will stimulate readers to learn more about the many issues touched upon, and that it will motivate other researchers to undertake further study of ice hockey.

HISTORY AND ACTIVITIES

ICORS (Icelandic Operations Research Society) was founded in January 1985. The membership quickly increased to just more than 100 members in the first five years, and has stayed relatively stable at around 100 ever since. The population of Iceland is only around 300,000 so one might not expect to find an OR society in such a small country. A part of the explanation is that ICORS is somewhat different from most of the other OR societies in that only a small number of the members are academics and that very few have a degree in OR. Many of the members have had one or two courses in OR, including a large number of the engineers, and they want to explore possible uses of OR methods in their firms or institutions. The concept of OR is relatively well known in Iceland for several reasons: one is that the concept of OR (“aðgerðarannsóknir” in Icelandic) is discussed in newspapers and magazines every now and then and another is that one of the early OR people was for a while Minister of Fisheries and a member of the parliament for many years.

ICORS arranges meetings approximately once every month during winter and publishes a newsletter in Icelandic.

ICORS collaborates with the Nordic OR societies, which have arranged biennial conferences, now under the name Nordic operations research society (NOAS), but formerly

NOAK. In 1980, an extra NOAK conference was held in Iceland between two regular ones.

ICORS is a member of the EURO (Association of European Operational Research Societies) and INFORMS (Institute for Operations Research and Management Sciences).

HONORARY MEMBERS

The ICORS has six honorary members:

1. Helgi Sigvaldason, is a pioneer in teaching OR in Iceland. He wrote the first text book on OR in Icelandic. He also applied OR methods to various practical projects in Iceland [1].
2. Frederick S. Hillier is a Professor of OR at Stanford University: Well known for his widely used text books on OR, his roots are Icelandic and he has contributed to the development of OR in Iceland.
3. Kjartan Jóhannson was one of the pioneers in OR in Iceland, and first worked as a consultant. Later he became a member of parliament and a minister, and he supported OR in different ways.
4. Þorkell Helgason was a pioneer in applying OR methods within the governmental sector in Iceland.
5. Páll Jensson is a Professor of OR at University of Iceland. He has been involved in various research projects and practical OR projects in Iceland [2,3].
6. Snjólfur Ólafsson, Professor of OR at University of Iceland, was the first president of ICORS. He has been involved in various research projects and practical OR projects in Iceland [4,5].

ICORS PRESIDENTS

ICORS has had three presidents from its establishment in 1985. The first president was Prof. Snjólfur Ólafsson. He was the

president for 17 years until Prof. Birna Kristinsdóttir took over in 2002. She was the president until 2007 when Prof. Hlynur Stefánsson took over.

EURO XXI CONFERENCE IN ICELAND

The EURO XXI Conference was held by ICORS in Reykjavik (July 2–5, 2006). The theme of the conference was “OR for better management of sustainable development.” The conference was a great success with 1541 delegates from 63 countries. In the following section we summarize some key information about the conference.

Organization

In 2003, at the EURO conference in Istanbul, ICORS was formally appointed to host the EURO XXI Conference in 2006 in Reykjavik, Iceland. The following members were appointed to the program committee: Tuula Kinnunen (chair), Gerhard-Wilhelm Weber (plenary chair), Raymond Bisdorff, Jean-Pierre Brans, Ulrike Leopold-Wildburger, Snjólfr Ólafsson, Maurice Shutler, Marino Widmer, and Martin Zachariassen. The following members were appointed to the organizing committee: Snjólfr Ólafsson (chair), Gülay Barbarosoglu, Magnús M. Halldórsson, Ingjaldur Hannibalsson, Thorkell Helgason, Páll Jensson, Tuula Kinnunen, Jakob Krarup, Birna P. Kristinsdóttir, Bjarni Kristjánsson, and Hlynur Stefánsson.

The program and organizing committees had four formal meetings to prepare the conference, one every year from 2003 to 2006.

Program and Scope of the Conference

Following the regular format for EURO conferences, the EURO XXI 2006 conference featured plenary, semiplenary, tutorial, keynote sessions and panels along with a large number of invited and contributed sessions on topic areas. The plenary sessions were given by the EURO 2006 Gold Medalist Luk van Wassenhove and the IFORS Distinguished Lecturer Saul Gass who gave a very informative talk titled “An annotated timeline

of operations research.” In total, there were 14 semiplenary sessions, 8 tutorial sessions, 5 keynote sessions, and 4 panel sessions. Other presentations were organized in 84 topic-specific streams containing 3–17 sessions each and in total 1477 papers were presented. A total of nine exhibitors attended the conference to display books and software. The conference was held at the University of Iceland in 47 meeting rooms spread across seven buildings. The sessions were organized in specific buildings, based on streams and subject themes.

The social program was very well attended. The welcome reception took place at the Blue Lagoon. However, due to the high number of participants it was impossible to take them all to the Blue Lagoon on the same day. Therefore half the participants went to the Blue Lagoon on Sunday and to a reception in Perlan (a popular restaurant with panorama view over entire Reykjavik) on Monday, and the other half in opposite order. The Soul Gass 7K Run took place with 27 participants, many of whom enjoyed using the outdoor swimming pools of Reykjavik afterwards. Finally the social program ended with the gala banquet, which was held in a place that could seat all the attending participants.

OR AT THE ACADEMIC LEVEL IN ICELAND

OR in Icelandic Universities

At the University of Iceland there are three faculty positions more or less devoted to OR: one in the Faculty of Mathematics, one in the Faculty of Engineering and one in the Faculty of Business and Economics. At Reykjavik University there are another three faculty positions devoted to OR. Introductory courses to OR are taught to approximately 250 students annually and several advanced courses are offered at undergraduate and graduate levels.

OR Students and Faculty Abroad

There are at least four members of ICORS who have OR/management science faculty positions in foreign universities, including

Georgia Institute of Technology, London School of Business, Stanford University, and University of Atlanta.

Quite a few students have completed MSc or PhD degrees in OR from various foreign universities, mostly in North America and Europe.

OR PROJECTS—SHORT HISTORY OF THE USE OF OR IN ICELAND

During the early years of the use of OR methods in Iceland (1965–1990) the main emphasis was on fishing and the fishing industry. This emphasis is not surprising since the fishing industry is one of the backbones of the Icelandic economy. The first major Icelandic OR model was created in 1966. The OR model was a simulation of the fishing and landing of herring, written in Fortran. The project was a collaboration between Icelandic and Danish scientists.

In 1969 a small group made a model for demersal fishing, mainly to estimate whether small or large trawlers would be more economical.

In the late seventies, Þorkell Helgason and others began to build different fisheries models for demersal fishing. These models have been used, both for academic studies and also directly by government authorities. In the beginning, OR people presented optimization models [6,7] but these were never accepted by people in the industry. The model that was used was a detailed simulation model [4] which was based on the data for the last few decades of fishing in Icelandic waters. At that time, this data was probably more extensive than that available in most other countries.

The stock size of demersal species is one of the basic elements of the model. The estimate of stock size is based on data on the catch in earlier years, divided by age. Extensive statistical analysis was performed in order to improve the estimation methods [8,9]. Also, some research work was done concerning stock estimation for whales.

Iceland is rich in energy, both in the form of waterfalls and geothermal power. Many projects, in the field of OR and related fields,

have been carried out in connection with energy.

In terms of Icelandic software related to ICORS, Maximal Software, Inc. is one of the leading providers of software for developing and formulating models in the field of optimization. Maximal Software Inc. is founded and owned by Bjarni Kristjánsson, who is an active participant in ICORS.

Over the last 10–15 years a number of companies specializing in OR or OR-related methods have been founded. The earliest companies include Mímisbrunnur ehf. and Bestun og ráðgjöf ehf. which later merged, forming a company called AGR ehf. AGR specializes in forecasting and inventory management. AGR has developed software that uses forecasting to create automatic purchase proposals for small- to medium-sized companies, with the goal of improving stock turnover and decreasing the stock in inventory. Other companies include Vaktaskipan ehf. which focuses on staff scheduling. There are also OR departments in a couple of the larger companies in Iceland. Marel Food System, a global provider of equipment and systems for the food processing industry, and Icelandair, the largest airline company in Iceland, both have OR departments and use OR methods to improve their products and services and to increase their revenue.

IFORS: BRINGING THE WORLD OF OR TOGETHER FOR 50 YEARS

ELISE DEL ROSARIO
One Small Step Forward Foundation,
Inc., Bagumbayan, Quezon City,
Philippines

GRAHAM RAND
Department of Management Science,
Lancaster University, Lancaster,
UK

Operational Research (OR) was born at the time of ideological confrontation at the end of the 1930s, but the International Federation of Operational Research Societies (IFORS) was born some 20 years later out of professional cooperation. IFORS officially came into existence in January 1959, as a result of discussions inaugurated at the first international conference, held in Oxford in 1957 [1].

COMPOSITION

Member Societies

Founded by the United States (ORSA Operations Research Society of America), United Kingdom (ORS Operational Research Society), and France (SOFRO Société Française de Recherche Opérationnelle) 50 years ago, IFORS is now composed of 50 active member societies. Table 1 shows the development of the federation as national societies joined IFORS. The national member societies represent some 25,000 individual members, ranging from 50 to 10,000 per society.

Regional Groups

In 1976, the Association of European Operational Research Societies (EURO) within IFORS was established. The Association of Latin–Ibero American Operations Research Societies (ALIO) was founded in 1982, followed immediately in 1985 by the Association of Asia–Pacific Operations Research Societies (APORS) within IFORS. The Association of North American Operations

Research Societies (NORAM) within IFORS (composed of the OR societies of Canada and the USA) was created so that a Vice President representing the region may be appointed to the IFORS Administrative Committee (AC).

Kindred Societies and International Affiliation

Bodies other than the national societies, such as the Airlines Group of the International Federation of Operational Research Societies (AGIFORS), the Mathematical Programming Society (MPS), and the Fellowship for Operational Research (FOR) were welcomed as kindred societies. IFORS joined four other international federations—the International Federation of Automatic Control (IFAC), the International Federation for Information Processing (IFIP), the International Federation for Mathematics and Computers in Simulation (IMACS), and the International Measurement Confederation (IMEKO) to form the Five International Associations Coordinating Committee (FIACC).

LEADERSHIP AND ORGANIZATIONAL STRUCTURE

The initial structure of IFORS did not require a President. The affairs of the federation were to be administered by a “foster” society for three-year periods. The statutes provided for a secretariat consisting of an executive officer (the secretary) and a treasurer; both nominated by the designated foster society. The initial foster society was the ORS in the UK, which appointed Sir Charles Goodeve Secretary. ORSA took over as foster society for 1962–1964, with Philip Morse as the secretary. A change in structure of the administration of IFORS came into effect in 1968, after France had taken its turn as the third foster society, with the creation of an AC. A further change was introduced, when the vice presidential component of the AC became four regional VPs, plus one VP-at-large, elected by the IFORS membership as a

Table 1. Growth of IFORS: Date of Joining of Each National Society

Year	OR Society	Year	OR Society
1959	France, United Kingdom, United States of America	1978	Singapore
1960	Australia, Belgium, Canada, India, The Netherlands, Norway, Sweden	1979	Austria
1961	Japan	1982	China, Portugal
1962	Argentina, Germany, Italy	1983	Hong Kong, Yugoslavia
1963	Denmark, Spain, Switzerland	1986	Iceland
1966	Greece, Ireland, Mexico	1988	Malaysia
1969	Brazil, Israel	1990	Philippines, Poland
1970	New Zealand	1992	Hungary
1972	Korea	1993	Bulgaria
1973	South Africa	1994	Croatia, Czech Republic, Slovakia
1975	Chile, Finland	1998	Belarus
1976	Egypt	2002	Bangladesh, ^a Colombia, Lithuania
1977	Turkey	2007	Slovenia
		2009	Uruguay, Iran

^a Bangladesh withdrew from IFORS in 2009.

Table 2. Presidents of IFORS

Period	President	Period	President
1959–61	Sir Charles Goodeve (United Kingdom)	1983–85	Heiner Muller Merbach (Germany)
1962–64	Philip Morse (United States of America)	1986–88	Jacques Lesourne (France)
1965–66	Marcel Boiteux (France)	1989–91	Bill Pierskalla (United States of America)
1967	Charles Salzmann (France)	1992–94	Brian Haley (United Kingdom)
1968–70	Alec Lee (Canada)	1995–97	Peter Bell (Canada)
1971–73	Arne Jensen (Denmark)	1998–2000	Andres Weintraub (Chile)
1974–76	Takehiko (Bill) Matsuda (Japan)	2001–03	Paolo Toth (Italy)
		2004–06	Thomas Magnanti (United States of America)
1977–79	David Hertz (United States of America)	2007–09	Elise del Rosario (Philippines)
1980–82	Roger Colcutt (United Kingdom)	2010–12	Dominique de Werra (Switzerland)

whole. The presidents of IFORS are as shown in Table 2 [2].

IFORS is run by a board composed of the representatives of each member country who vote on major issues confronting IFORS. The AC is responsible for the execution of activities and drafting of proposals for approval by the board. The AC is elected for a period of 3 years, except for the treasurer whose term is renewable twice at the most. The secretary's location corresponds to the headquarters of IFORS.

TRIENNIAL CONFERENCES

The 1957 Oxford Meeting was followed by preparation of the statutes, which set the purpose as “the development of operational research as a unified science and its advancement in all nations of the world.” The statutes contain a provision that in all formal votes taken by the board, the voting strength of each member society is in proportion to the square root of the qualified membership. This is meant to give greater weight to larger societies but not to overwhelm the

smaller societies. The first conference was followed by a series of triennial conferences of which eight have been held in Europe, five in the North American region, two in the Asia–Pacific region, and one each in Africa and Latin America.

PUBLICATIONS

International Abstracts in Operations Research (IAOR)

The history of *International Abstracts in Operations Research* (IAOR) goes back to 1958 when Hugh Miser, the then secretary of ORSA, proposed to Sir Charles Goodeve that one of the early items of IFORS business should be the possibility of funding and operating a journal that would bring all “unclassified” OR work to the attention of the worldwide OR community; IAOR was first published in 1961 [3]. The method of collecting, indexing, and publishing material did not change until 2007 when the plan to respond to the challenges and opportunities of the internet were put in motion. The IAOR system development sought to modernize IAOR by making it an “online-based” rather than a “print-based” product. Development activities to improve speed and comprehensiveness in acquiring abstracts and allowing access to online subscribers were carried out. With effect from the third issue of 2009, all issues are being produced using the “Editor’s Workbench” which facilitates the electronic capture of materials.

International Transactions in Operational Research (ITOR)

From the first conference in 1957 up to the Athens Conference in 1990, a volume of proceedings was published. These volumes include a selection of papers presented, as well as records of discussions at workshops. After the 1993 Lisbon Conference and under the editorship of Peter Bell, the first volume of the *International Transactions in Operational Research* (ITOR) was published. A 2006 review committee to address the problems being encountered by the journal proposed a strategic plan that began to

be implemented in 2007. Various innovations on the composition of the editorial board and launching of special issues have resulted in increased paper submissions. An electronic editorial office was launched in 2008, enabling a decreased refereeing time and in general, greater effectiveness of the refereeing procedure. In 2003–2006, ITO published citations of 23 inductees into the IFORS OR Hall of Fame.

IFORS DISTINGUISHED LECTURE (IDL)

In 1999 IFORS established a International Federation of Operational Research Societies Distinguished Lectures (IDL) program to recognize distinguished OR scholars and analysts and support member societies and regional groupings. Through this program, IFORS sponsors lectures by distinguished OR scholars and analysts at conferences of its regional groupings. So far, the nomination, screening, and selection process have yielded 29 IDL.

DEVELOPING COUNTRY ACTIVITIES

The IFORS 1975 Japan Conference with the theme “OR in the Service of Developing Economies” put OR for development on the IFORS agenda. The 1984 Washington Conference started several initiatives in the area of OR for development. OR practice in developing countries continues to be one of the focal points of IFORS.

ICORD

In December 1992, participants of the first International Conference on Operations Research for Development (ICORD) held in Ahmedabad, India, agreed on recommendations on how OR could best be advanced in developing countries. The Ahmedabad Declaration, as it has become known, called for a range of actions from IFORS to support and strengthen OR in developing countries. Successive ICORDs were held in Rio de Janeiro (1996), Manila (1997), Berg-en-dal (2001), Jamshedpur (2005), and Fortaleza (2008). A call for proposals that would lead to

the organization of smaller workshops leading up to the next ICORD was subsequently issued. The new structure aims to achieve a greater momentum for the ORD (Operations Research for Development) program through greater frequency and visibility of actions and improved focus for ORD activities on selected problem-oriented themes [4], and is financially supported by IFORS.

IFORS Prize for OR in Development

The IFORS Prize, awarded at the triennial conferences, aims to bring to the fore outstanding works that show how OR has been used to help specific organizations in their decision-making process within the context of a developing country and in emphasizing developmental issues.

Africa Initiatives

With the help of EURO, IFORS has initiated several activities, including sponsoring conferences and scholarships in the African continent in an effort to address the lack of organized OR activity in the area. IFORS has provided funding for the Operations Research Practice for Africa (ORPA), conferences for 2007 (ORPA2), and 2008 (ORPA4). While ORPA2 focused on applications of OR outside South Africa, ORPA 4 focused on the use of operations research to address urban transportation and water resource management issues in Africa. During the 2008 IFORS Conference held in South Africa, EURO and IFORS jointly sponsored 25 participants coming from Africa and other developing countries. The Local Organizing Committee screened and selected from among the applicants the recipients of the registration, travel, and accommodation funding as required.

OR EDUCATION

Teachers' Workshops

One of the initiatives that came out of the 1984 IFORS triennial conference in Washington was the launching of teachers' workshops which aimed to increase the use of OR as a practical tool for decision makers in Asia by

influencing the way OR is taught. Regional workshops for teachers of OR in developing countries were subsequently held in Ahmedabad (1986), Mumbai (1987), Kuala Lumpur (1988), Singapore (1989), Jakarta (1990), and Manila (2004).

More recently, IFORS cosponsored the teachers' workshops initiative of the US national society, INFORMS (Institute for Operations Research and the Management Sciences), during the 2008 Latin-Ibero American Congress on Operations Research (CLAIO) held in Colombia and the 2009 APORS conference held in India. This program aims to hone the skills of OR teachers and improve their teaching effectiveness. Under this program, speaker expenses were paid by the sponsoring organizations.

Student Programs

Since 2000, IFORS has continually provided scholarship funds for participants to join summer institutes and workshops as part of the regional activities. So far, several scholars have been sent to the EURO, ALIO, and APORS workshops. The sponsorship is aimed at encouraging the establishment of groups of promising young OR scientists who will continue to work and network in the future. Under this program, IFORS pays for the air fare of the IFORS scholars while the local organizers provide the accommodation, program fees, and living expenses. IFORS also contributes to the expenses of the local organizers.

Most recently, IFORS scholars were sent, and a contribution to the local accommodation expenses was made, to the ELAVIO (Escuela Latinoamericana de Verano de Investigacion Operativa) 2008 in Peru and the ELAVIO 2009 in Mexico. Two IFORS scholars were sponsored to the EURO Summer–Winter Institutes (ESWI) 2009 in Spain. IFORS has also sponsored the EURO Working Group workshop on *OR for Developing Countries* by helping to defray expenses of the participants needing support and seconding a speaker to the workshop. Held regularly, the workshop provides a forum for doctoral students and others involved in OR and development to share and discuss their

research activities; encourages students to establish and maintain a research network; and fosters a research environment to support career development in a practical OR discipline.

Web-Based Educational Resources

As part of fostering excellence in OR education, the *Educational Resources* portion of the IFORS website is being developed to gather and make available on the web, high quality educational material such as case studies, methodological readings, and algorithms. This work is in progress. The other component is the *tutORial*, which has been completed and features a collection of interactive web-based tutorial modules on generic OR topics.

IFORS WEBSITE

Apart from serving as a valuable resource for the OR practitioner and academic, the IFORS website <http://www.ifors.org>, aims to be a key tool in promoting OR internationally. In line with this, the site includes information about local and international conferences, activities of member societies, updates on IFORS committee activities, links to national societies and regional groupings, and all IFORS newsletter issues. The website is kept current through the constant update of information and continuous upgrade of layout, navigation, news management system, RSS feeds, search and translation facilities. An area for members is available for online voting and discussions [5].

IFORS NEWS

The IFORS News takes over from the IFORS Bulletin last published in 2000. The IFORS News is published quarterly, featuring events from member societies, reports from the IFORS scholars, perspectives from IFORS distinguished lecturers, past and present IFORS officers, write-ups of IFORS prize-winning papers, and scholarly takes on various OR topics. It has also incorporated the newsletter of the Developing Countries Committee, which aimed to keep people in contact between the ICORD conferences. All the IFORS News issues are downloadable from the IFORS website and alerts are sent to the national societies when the issues become available. Only the annual report issues are printed for distribution at conferences and sent to the members by post.

IMPLEMENTING THE SIMPLEX METHOD

MATTHEW J. SALTZMAN
Department of Mathematical
Sciences, Clemson University,
Clemson, South Carolina

Linear programs (LPs) are the most widely employed optimization models. Throughout the history of operations research, the simplex method has been the workhorse algorithm for solving LPs.

Linear programming was first formalized by Dantzig [1]. The simplex method was originally presented at a 1949 conference and published in the proceedings [2]. One of the first published reports of a computer implementation of the simplex method for linear programming appeared in 1953 [3]. It compared the simplex method to two other algorithms, solving problems of up to 10 variables and 10 inequality constraints on the SEAC computer at the US National Bureau of Standards (now the National Institute of Standards and Technology). The basic revised simplex method—the foundation of all efficient simplex implementations—is described by Dantzig and Orchard-Hays [4]. Development of more efficient implementation techniques proceeded apace through the 1970s, but performance reached something of a plateau after that.

In 1979, Khachian [5] announced a polynomial-time algorithm for linear programming. (Most variations of the simplex method are known to require worst case running time that grows exponentially with problem size—none are known to be polynomial.) However, Khachian’s “ellipsoid method” cannot be implemented efficiently enough to compete with simplex codes on practical problems. In 1984, Karmarkar announced (with great fanfare) his interior-point algorithm [6], for which he claimed a highly efficient implementation. His announcement was received amid much

controversy, and was taken as a challenge by simplex implementers.

Dramatic improvements in both interior-point and simplex algorithms followed during the late 1980s and the 1990s. Bixby [7] details the history of computational LP from its origins to the turn of the millennium. Bixby reports that, from the first release of the CPLEX solver in 1988 through 2002, the speed of CPLEX’s simplex implementation (controlling for hardware advances) has improved by a factor of 50. Since then, progress seems to have stabilized again, though incremental improvements continue.

The basic simplex method is a simple and straightforward algorithm. But modern efficient implementations represent a tour de force of algorithm engineering and numerical methods designed to exploit opportunities for efficiency wherever they arise.

This article surveys the key techniques necessary to implement a robust, efficient simplex code. These techniques support the following strategic design elements:

- compute only what you need;
- minimize the number of iterations;
- update rather than recompute;
- exploit sparsity ruthlessly;
- control the growth of roundoff errors.

Complete descriptions of the detailed data structures and algorithms required for implementing the techniques described here are much too involved to include in this short article at a level of detail suitable for implementation. Resources for programmers desiring to create a simplex code are listed at the end of the article.

THE BOUNDED-VARIABLE LINEAR PROGRAM

The standard form of linear program for implementation handles implicitly both

upper and lower bounds as well as free variables. For *decision variables* $\mathbf{x} \in \mathbb{R}^n$ and constants $\mathbf{c}, \mathbf{l}, \mathbf{u} \in \mathbb{R}^n$, $\mathbf{b}_l, \mathbf{b}_u \in \mathbb{R}^m$, and $A \in \mathbb{R}^{m \times n}$, the bounded-variable linear program is:

$$\begin{aligned} & \text{minimize} && \mathbf{c}^T \mathbf{x} \\ & \text{subject to} && \mathbf{b}_l \leq A\mathbf{x} \leq \mathbf{b}_u \\ & && \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, \end{aligned} \quad (1)$$

where $l_j, u_j, (\mathbf{b}_l)_i$, and $(\mathbf{b}_u)_i$ need not be finite, but $l_j = u_j$ and $(\mathbf{b}_l)_i = (\mathbf{b}_u)_i$ are permitted. Most LP codes transform the input problem into one of two internal forms:

- A nonhomogeneous form (used by CPLEX, among other solvers):

$$\begin{aligned} & \text{minimize} && \mathbf{c}^T \mathbf{x} \\ & \text{subject to} && A\mathbf{x} + I\mathbf{s} = \mathbf{b} \\ & && \mathbf{l}_x \leq \mathbf{x} \leq \mathbf{u}_x, \mathbf{l}_s \leq \mathbf{s} \leq \mathbf{u}_s, \end{aligned}$$

where b_i is $(\mathbf{b}_u)_i$ or $(\mathbf{b}_l)_i$ and the *slack* (or *logical*) variable s_i is nonnegative for less-or-equal constraints, nonpositive for greater-or-equal constraints, nonnegative and bounded for range constraints, or fixed to zero for equality constraints. (Obvious variations involving choice of b_i and signs on the slacks are also possible).

- A homogeneous form (used by the COIN-OR LP (CLP) solver):

$$\begin{aligned} & \text{minimize} && \mathbf{c}^T \mathbf{x} \\ & \text{subject to} && A\mathbf{x} - I\mathbf{s} = \mathbf{0} \\ & && \mathbf{l}_x \leq \mathbf{x} \leq \mathbf{u}_x, \mathbf{b}_l \leq \mathbf{s} \leq \mathbf{b}_u. \end{aligned}$$

Both of these forms can be represented in standard bounded-variable form by merging the original slack and decision variables into a single vector $\mathbf{x}$:

$$\begin{aligned} & \text{minimize} && \mathbf{c}^T \mathbf{x} \\ & \text{subject to} && A\mathbf{x} = \mathbf{b} \\ & && \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}. \end{aligned} \quad (2)$$

We denote the set of row indices by $\mathcal{I} = \{1, 2, \dots, m\}$ and the set of column indices by $\mathcal{J} = \{1, 2, \dots, n\}$. A *basis* for Equation (2) is defined by a partition of $\mathcal{J}$ into ordered subsets $\mathcal{B}, \mathcal{L}, \mathcal{U}, \mathcal{F}$, called the *basis header*. Up to

column ordering, Equation (2) can be rewritten as

$$\begin{aligned} & \text{minimize} && \zeta = \mathbf{c}_B^T \mathbf{x}_B + \mathbf{c}_L^T \mathbf{x}_L + \mathbf{c}_U^T \mathbf{x}_U \\ & && + \mathbf{c}_F^T \mathbf{x}_F \\ & \text{subject to} && B\mathbf{x}_B + L\mathbf{x}_L + U\mathbf{x}_U + F\mathbf{x}_F = \mathbf{b} \quad (3) \\ & && \mathbf{l}_B \leq \mathbf{x}_B \leq \mathbf{u}_B, \\ & && \mathbf{l}_L \leq \mathbf{x}_L \leq \mathbf{u}_L, \\ & && \mathbf{l}_U \leq \mathbf{x}_U \leq \mathbf{u}_U, \\ & && \mathbf{l}_F \leq \mathbf{x}_F \leq \mathbf{u}_F, \end{aligned}$$

where the columns of the submatrix B of A are indexed by the members of $\mathcal{B}$, etc. The partition must satisfy the following criteria:

- $|\mathcal{B}| = m$ and B has rank m ;
- all members of $\mathcal{L}$ have finite lower bounds;
- all members of $\mathcal{U}$ have finite upper bounds and;
- all members of $\mathcal{F}$ have infinite upper and lower bounds.

The order of indices in each set is arbitrary but static.

We use the following notation to describe these sets: For $\beta = 1, 2, \dots, m$, let $j(\beta)$ be the original index value appearing in position β in $\mathcal{B}$, and $\beta(j)$ be the position in $\mathcal{B}$ containing index j . The members of $\mathcal{L}$ are indexed similarly by $\lambda = 1, 2, \dots, n_L = |\mathcal{L}|$; $\mu = 1, 2, \dots, n_U = |\mathcal{U}|$, and $\phi = 1, 2, \dots, n_F = |\mathcal{F}|$. It is occasionally useful to refer to the nonbasic indices as a group. Thus, we define $\mathcal{N} = \mathcal{L} \cup \mathcal{U} \cup \mathcal{F}$, $A = [BLUF] = [BN]$ (up to column order), and index the entries of $\mathcal{N}$ by $v = 1, 2, \dots, n_N = n_L + n_U + n_F = n - m$. The variables $\mathbf{x}$ and rim vectors $\mathbf{l}, \mathbf{u}$, and $\mathbf{c}$ are partitioned similarly.

Associated with each possible partition is a *basic solution* defined as follows:

$$\mathbf{x}_L = \mathbf{l}_L, \quad (4)$$

$$\mathbf{x}_U = \mathbf{u}_U, \quad (5)$$

$$\mathbf{x}_F = \mathbf{0}, \quad (6)$$

$$\mathbf{x}_B = B^{-1}\mathbf{b} - B^{-1}L\mathbf{x}_L - B^{-1}U\mathbf{x}_U - B^{-1}F\mathbf{x}_F \quad (7)$$

$$= B^{-1}\mathbf{b} - B^{-1}L\mathbf{l}_L - B^{-1}U\mathbf{u}_U \quad (8)$$

$$= B^{-1}\hat{\mathbf{b}} \quad (9)$$

$$\begin{aligned} \zeta &= \mathbf{c}_B^T B^{-1}\mathbf{b} + (\mathbf{c}_L^T - \mathbf{c}_B B^{-1}L)\mathbf{x}_L \\ &\quad + (\mathbf{c}_U^T - \mathbf{c}_B^T B^{-1}U)\mathbf{x}_U \\ &\quad + (\mathbf{c}_F^T - \mathbf{c}_B^T B^{-1}F)\mathbf{x}_F \end{aligned} \quad (10)$$

$$\begin{aligned} &= \mathbf{c}_B^T B^{-1}\mathbf{b} + (\mathbf{c}_L^T - \mathbf{c}_B B^{-1}L)\mathbf{l}_L \\ &\quad + (\mathbf{c}_U^T - \mathbf{c}_B^T B^{-1}U)\mathbf{u}_U. \end{aligned} \quad (11)$$

If $\mathbf{l}_B \leq \mathbf{x}_B \leq \mathbf{u}_B$, then this is a *basic feasible solution* (BFS). The variables in $\mathcal{B}$ are referred to as *basic*, those in $\mathcal{L}$ and $\mathcal{U}$ are *nonbasic* at their lower and upper bounds, respectively, and those in $\mathcal{F}$ are *superbasic*. More generally, a *superbasic variable* is a nonbasic variable that is not equal to either bound; a *superbasic solution* is one that contains superbasic variables.

In fact, the values of $\mathbf{x}_F$ are arbitrary. The basis headers $\mathcal{B}, \mathcal{L}, \mathcal{U}, \mathcal{F}$ together with Equations (4), (5), (7), and (10) define a family of superbasic solutions parameterized by $\mathbf{x}_F$. The convention is to set $\mathbf{x}_F = \mathbf{0}$, as this simplifies the computation of $\mathbf{x}_B$ and ζ to Equations (8) and (11), respectively.

THE BOUNDED-VARIABLE SIMPLEX METHOD

The bounded-variable simplex method works as follows:

1. *Initialization*. Identify a BFS (see the section titled “Phase 1”). Factor B , solve $B\mathbf{x}_B = \hat{\mathbf{b}} = \mathbf{b} - L\mathbf{l}_L - U\mathbf{u}_U$, and solve $B^T\mathbf{y} = \mathbf{c}_B$ (see the section titled “Basis Factorization”).
2. *Optimality Test/Entering Variable Selection (Pricing)*. If $\mathbf{c}_L - L^T\mathbf{y} \geq \mathbf{0}$, $\mathbf{c}_U - U^T\mathbf{y} \leq \mathbf{0}$, and $\mathbf{c}_F - F^T\mathbf{y} = \mathbf{0}$, then *stop* (the current BFS is optimal). Otherwise, select an index $j^* \in \mathcal{N}$ that violates these conditions. Let $\bar{c}_{j^*} = c_{j^*} - \mathbf{y}^T A_{j^*}$.

3. Direction/Ratio Test/Leaving Variable Selection.

- If $j^* \in \mathcal{L}$, solve $B\mathbf{d}_B = -L_{\cdot j^*}$.
- If $j^* \in \mathcal{U}$, solve $B\mathbf{d}_B = U_{\cdot j^*}$.
- If $j^* \in \mathcal{F}$ and $(\mathbf{c}_F - F^T\mathbf{y})_{\phi(j^*)} < 0$, solve $B\mathbf{d}_B = -F_{\cdot \phi(j^*)}$.
- If $j^* \in \mathcal{F}$ and $(\mathbf{c}_F - F^T\mathbf{y})_{\phi(j^*)} > 0$, solve $B\mathbf{d}_B = F_{\cdot \phi(j^*)}$.

Compute

$$\begin{aligned} \beta^* &= \arg \min_{\beta \in \mathcal{B}} \left\{ \min_{\beta: (\mathbf{d}_B)_\beta < 0} \frac{(\mathbf{x}_B)_\beta - (\mathbf{l}_B)_\beta}{-(\mathbf{d}_B)_\beta}, \right. \\ &\quad \left. \min_{\beta: (\mathbf{d}_B)_\beta > 0} \frac{(\mathbf{u}_B)_\beta - (\mathbf{x}_B)_\beta}{(\mathbf{d}_B)_\beta} \right\} \\ \alpha^* &= \begin{cases} \frac{(\mathbf{x}_B)_{\beta^*} - (\mathbf{l}_B)_{\beta^*}}{-(\mathbf{d}_B)_{\beta^*}} & \text{if } (\mathbf{d}_B)_{\beta^*} < 0 \\ \frac{(\mathbf{u}_B)_{\beta^*} - (\mathbf{x}_B)_{\beta^*}}{(\mathbf{d}_B)_{\beta^*}} & \text{if } (\mathbf{d}_B)_{\beta^*} > 0 \end{cases} \end{aligned}$$

$$\gamma^* = \min\{u_{j^*} - l_{j^*}, \alpha^*\}$$

If $\gamma^* = \infty$, then *stop* (the LP is unbounded).

4. Pivot and Update.

- (a) Set $\mathbf{x}_B := \mathbf{x}_B + \gamma^* \mathbf{d}_B$.
- (b) If $\gamma^* = u_{j^*} - l_{j^*}$ then move j^* from $\mathcal{L}$ to $\mathcal{U}$ or vice versa. Otherwise ($\gamma^* = \alpha^* < u_{j^*} - l_{j^*}$):
 - Add $j(\beta^*)$ to $\mathcal{L}$ (if $(\mathbf{d}_B)_{\beta^*} < 0$) or $\mathcal{U}$ (if $(\mathbf{d}_B)_{\beta^*} > 0$), and set the β^* entry of $\mathcal{B}$ to j^* .
 - Set $(\mathbf{x}_B)_{\beta^*} := \alpha^*$.
- (c) Set $\mathbf{y} := \mathbf{y} + \tau^* B_{\cdot \beta^*}^{-T}$, where $\tau^* = \bar{c}_{j^*}/(\mathbf{d}_B)_{\beta^*}$.
- (d) Set $\zeta := \zeta + \gamma^* \bar{c}_{j^*}$.
- (e) Replace $B_{\cdot \beta^*}$ with A_{j^*} and update the factorization of B .
- (f) Go to Step 2.

Pricing. The values $\mathbf{y} = B^{-T}\mathbf{c}_B$ computed in Step 2 are called the *shadow prices* of the constraints. As long as the current basis remains feasible for small changes in b_i , y_i is the rate of change of ζ per unit increase in b_i . The values $\bar{\mathbf{c}} = \mathbf{c} - A^T\mathbf{y}$ are referred to as

reduced costs of the variables. For $j \in \mathcal{N}$, $\bar{c}_j$ is the rate of change of ζ per unit increase in x_j , while maintaining feasibility with respect to the constraints $A\mathbf{x} = \mathbf{b}$, that is, per unit step in the direction $\mathbf{d} = (\mathbf{d}_B, \mathbf{d}_N)$, where $\mathbf{d}_N$ is a unit vector with ± 1 in position $\nu(j^*)$ (depending on whether x_{j^*} is increasing or decreasing).

There are usually several nonbasic variables that violate the optimality conditions in Step 2. The section titled “Pricing” describes several rules for choosing among those candidates.

Ratio Test. Note that a variable in the basis with infinite lower and upper bounds never leaves.

Ties for leaving variable may occur if more than one variable reaches a bound simultaneously. If any basic variable is equal to one of its bounds, the basis is *degenerate*. In this case, it is possible that $\gamma^* = 0$, in which case the pivot is called *degenerate* as well. In the absence of degenerate pivots, the algorithm terminates in Step 2 or Step 3 after a finite number of iterations. Modifications to handle degeneracy are described in the section titled “Degeneracy”.

Pivot. The update of B in Step 4 involves replacing the column of B corresponding to the variable leaving the basis with the column of A corresponding to the entering variable.

Note that $B\mathbf{d}_B = \pm A_{j^*}$ where the sign depends on whether the entering variable is increasing or decreasing. For simplicity, in the remainder of this discussion and in the sections titled “Steepest Edge Pricing” and “Basis Update,” we take $B\mathbf{d}_B = -A_{j^*}$. Then the update can be written as $B := BE$, where E is an *eta matrix* (η -matrix), that is, an identity matrix with one column replaced:

$$E = I - (\mathbf{d}_B + \mathbf{e}^{\beta^*}) (\mathbf{e}^{\beta^*})^T. \quad (12)$$

The effect of post-multiplying B by E is to replace the β^* column of B by A_{j^*} .

Refactoring the updated basis at every iteration would be impractical. Techniques for updating the factorization after changing

B are described in the section titled “Basis Update.”

Reducing the number of iterations is accomplished through the initialization step, the pricing step, and mitigation of degeneracy in the selection of the leaving variable. Also, the dual simplex method (see the section titled “The Bounded-Variable Dual Simplex Method”) is more efficient for many problems.

In general, the most costly operations of each iteration are the pivot/update and the direction computation (see the section titled “Sparsity and Linear Algebra”).

Roundoff control is accomplished by regularly recomputing from scratch values that are computed using updates and by careful selection of tolerances for making finite-precision comparisons (see the section titled “Controlling Roundoff Errors”).

Phase I. The problem of finding a starting BFS is usually solved using a two-phase approach. Phase II is the algorithm described above. Phase I implements the same approach, applied to a modified problem with a known starting BFS and an objective for which optimality is achieved when a BFS for the original problem is found or the original problem is proved to be infeasible.

For the bounded-variable LP (2), a known-feasible phase I problem and starting BFS can be constructed by selecting an arbitrary basis B , then fixing the nonbasic variables as follows:

- Let $j \in \mathcal{L}$ if $l_j > -\infty$ and $c_j \geq 0$ or if $u_j = \infty$.
- Let $j \in \mathcal{U}$ if $u_j < \infty$ and $c_j < 0$ or if $l_j = -\infty$.
- Let $j \in \mathcal{F}$ if $l_j = -\infty$ and $u_j = \infty$.

Next, temporarily replace bounds on $x_j, j \in \mathcal{B}$ so that basic variables that violate their original bounds are feasible and set the objective coefficients to push those variables toward their original bounds.

- If $x_j > u_j$, $l'_j := u_j$, $u'_j := \infty$ and choose $c'_j > 0$.
- If $x_j < l_j$, $u'_j := l_j$, $l'_j := -\infty$ and choose $c'_j > 0$.

- Otherwise, $l'_j := l_j$ and $u'_j := u_j$, and set $c'_j = 0$.

Numerous variations on this basic idea are possible.

A simple choice for initial $\mathcal{B}$ is the basis consisting of the slack variables added to LP (1) to produce LP (2). Numerous other methods for selecting $\mathcal{B}$ from among the original problem variables have been proposed as well. These generally go by the name *basis crashing*. Several crashes are described in Ref. 8, including those from Refs 9 and 10.

Pricing

The entering-variable selection rule that is presented in most expositions of the simplex method (including Dantzig's seminal book [11]) is to choose the entering variable that reduces the objective function the most per unit change in the entering variable. This rule (known as *Dantzig pricing*) selects the largest magnitude reduced cost among the negative reduced costs for variables at their lower bounds, positive reduced costs for variables at their upper bounds, and nonzero reduced costs for superbasic variables.

In early implementations, pricing all nonbasic variables was considered too expensive, so techniques were developed to avoid full pricing. These ideas reduced the cost per iteration, but did not address the issue of reducing the iteration count. The main techniques were combinations of *partial pricing* and *multiple pricing* (see the section titled "Partial Pricing and Multiple Pricing").

More recently, pricing techniques have been developed on the basis of choosing the entering variable that reduces the objective function the most per unit step in the corresponding direction. These *steepest edge pricing* methods require complete pricing at every iteration, but in general, substantially reduce the number of iterations required (see the section titled "Steepest Edge Pricing").

Partial Pricing and Multiple Pricing. In *partial pricing*, a contiguous subset of nonbasic variables is considered and the one with the best reduced cost is selected. In the next iteration, the next block is considered.

In *multiple pricing*, a subset of candidate nonbasic variables is considered, and the subproblem consisting of those variables plus the current basic variables is solved to optimality. Then a new subset is selected.

Numerous variations and combinations of these themes have been implemented, with varying degrees of success. For example, starting with a block of 100 variables, one might select the 10 most promising candidates, iterate considering only those candidates and the current basic variables until that subproblem is optimized, then move on to the next block of 100 variables.

One difficulty with using reduced cost as a selection criterion is that the reduced cost does not always correlate well with the actual decrease in objective value resulting from the chosen pivot. *Largest decrease* pricing looks at the actual decrease in the objective function resulting from pivoting in the candidate variable. This technique is far too expensive to apply in practice, because it requires a ratio test for every variable considered (although it can work reasonably effectively with multiple pricing).

Another difficulty with reduced costs is that they are not scale invariant. That is, scaling columns changes the reduced costs proportionally.

Steepest Edge Pricing. In *steepest edge* pricing, the direction vector $\mathbf{d} = (\mathbf{d}_B, \mathbf{d}_L, \mathbf{d}_U, \mathbf{d}_F)$ for each candidate variable is normalized. The nonbasic part $(\mathbf{d}_L, \mathbf{d}_U, \mathbf{d}_F)$ is a (positive or negative) unit vector, so $\|\mathbf{d}\|^2 = \|\mathbf{d}_B\|^2 + 1$. The entering variable is the one with the best value of $\mathbf{c}^T \mathbf{d} / \|\mathbf{d}\|$. It is easy to see that these weights are scale invariant.

Computing the norms and descent rates from scratch at each iteration would be impractically expensive, but there is an efficient update procedure [12]. Following the development in Ref. 13, suppose we know

$$\delta_j = \|\mathbf{d}_B^j\|^2 = \|B^{-1}A_{\cdot j}\|^2, \quad j \in \mathcal{N},$$

the squared norms of the basic portions of direction vectors used in the previous iteration, in which x_{j^*} entered and x_{i^*} left the basis. For convenience, denote $\beta^* = \beta(i^*)$.

Recall that the current basis matrix is formed from the previous one by $B := BE$ where the eta matrix E is formed from the identity by replacing a column, as in Equation (12). Then E^{-1} is also an eta matrix with the same column replaced:

$$E^{-1} = I + \frac{1}{(\mathbf{d}_B)_{\beta^*}} (\mathbf{d}_B - \mathbf{e}^{\beta^*}) (\mathbf{e}^{\beta^*})^T. \quad (13)$$

Thus the updated basic squared norm is

$$\begin{aligned} \delta_j &:= (\mathbf{A}_j)^T B^{-T} E^{-T} E^{-1} B^{-1} \mathbf{A}_j \\ &= (\mathbf{A}_j)^T B^{-T} \left(I + \frac{1}{(\mathbf{d}_B)_{\beta^*}} (\mathbf{e}^{\beta^*}) \right. \\ &\quad \times (\mathbf{d}_B - \mathbf{e}^{\beta^*})^T \Big) \\ &\quad \times \left(I + \frac{1}{(\mathbf{d}_B)_{\beta^*}} (\mathbf{d}_B - \mathbf{e}^{\beta^*}) (\mathbf{e}^{\beta^*})^T \right) B^{-1} \mathbf{A}_j. \end{aligned}$$

Let $\mathbf{v} = B^{-T} \mathbf{e}^{\beta^*}$ and $\mathbf{w} = B^{-T} \mathbf{d}_B$. Expanding the product above and substituting $\mathbf{v}$ and $\mathbf{w}$, the updated basic squared norms are computed from the previous values by

$$\begin{aligned} \delta_j &:= \delta_j - 2 \frac{(\mathbf{A}_j)^T \mathbf{v} (\mathbf{w} - \mathbf{v})^T \mathbf{A}_j}{(\mathbf{d}_B)_{\beta^*}} \\ &\quad + \left((\mathbf{A}_j)^T \mathbf{v} \right)^2 \frac{\|\mathbf{d}_B - \mathbf{e}^{\beta^*}\|^2}{(\mathbf{d}_B)_{\beta^*}^2}. \end{aligned}$$

Utilizing the update procedure requires maintaining complete prices at every iteration, and the additional cost of computing $\mathbf{w}$, plus the inner products involving $\mathbf{w}$ for columns where $(\mathbf{A}_j)^T \mathbf{v}$ is nonzero. (For sparse problems, $(\mathbf{A}_j)^T \mathbf{v}$ is frequently zero.) Also, memory is required for δ and the initial value of δ must be computed. The reduction in the average number of iterations versus the reduced-cost pricing methods, however, is worth the increase in cost of each iteration when the update procedure is used.

Forrest and Goldfarb [14] describe techniques to maintain the exact norms in a subspace of the variables, which they call “projected steepest edge” techniques. A dynamic projected steepest edge method maintains exact norms on a subset of

variables that can grow or shrink over the course of the algorithm.

Devex and Other Pricing Techniques. Although it was developed first, *Devex pricing* [15] can be viewed as an approximation of the steepest edge prices with a more efficient procedure. Benichou *et al.* [16] developed a modification of Devex that can be incorporated into a partial/multiple scheme. Swietanowski [17] proposes a different steepest edge approximation. Maros [8] generalizes all of the aforementioned techniques into a general framework for implementing pricing strategies.

Degeneracy

If there are ties for the leaving variable (multiple choices for β^*), then the simplex method can make a sequence of *degenerate pivots* with step size $\gamma^* = 0$, visiting a collection of *degenerate bases* (multiple bases describing the same BFS, where some basic variables take on values equal to their lower or upper bounds), and returning to a basis that has been visited previously. Thus, it is possible for the simplex method to cycle forever without terminating.

Cycling is extremely rare in practice. For highly degenerate problems, however, *stalling* (long sequences of degenerate pivots) is a frequent occurrence. Several anti-cycling techniques are known to guarantee termination of the simplex method in theory, including *random perturbation* (the “guarantee” here is probabilistic), *lexicographic perturbation*, and *Bland’s rule*.

As a practical matter, anti-degeneracy techniques add complexity to each iteration and interfere with other techniques designed to reduce the iteration count. For example, Bland’s rule dictates both entering and leaving variables, thus destroying any benefit from advanced pricing techniques. Most such techniques can be enabled when stalling is encountered and disabled when a positive reduction is made in the objective value.

The theoretical anti-cycling measures are generally not that effective in practice and they can be subject to numerical difficulties.

Several practical anti-degeneracy techniques are described in Ref. 8.

- When degeneracy is detected, tests on the entering column can be performed to identify and avoid columns that are guaranteed to result in degenerate pivots, because the pivot element corresponding to a degenerate variable is nonzero with the appropriate sign. Identifying columns that are guaranteed not to result in degenerate pivots is more difficult. However, Raymond *et al.* [18] describe techniques for selecting subproblems (rows and columns) that are likely to exhibit good behavior, and they describe computational experiments indicating that the effort invested yields improvements in number of pivots and overall solution time.
- The “ad hoc” method of Wolfe [19] systematically introduces “virtual perturbations” of the degenerate current basic values so that the basic direction is nondegenerate for those variables. Ryan and Osborne [20] provide a nice interpretation of Wolfe’s method as seeking a direction of unboundedness with respect to the degenerate constraints. They describe an implementation that effectively adds no overhead to the simplex method. Ryan and Osborne’s implementation marks the degenerate variables, then pivots against only the degenerate constraints until optimality is proved, a nondegenerate direction is found, or a degenerate pivot is encountered in the restricted constraint set. If the latter occurs, the problem is restricted recursively to the subset of degenerate constraints with respect to the current direction.
- The EXPAND method of Gill *et al.* [21] uses an expanding feasibility tolerance (see the section titled “Tolerances”) to avoid altogether the need to consider degeneracy.
- Direct perturbation of the degenerate basic variable values or their bounds during the ratio test is also effective. If the algorithm terminates with

perturbations activated, the problem is re-optimized with the perturbations removed.

THE BOUNDED-VARIABLE DUAL SIMPLEX METHOD

For many problems, a variation on the simplex method performs better than the version described above. The dual simplex method starts with a possibly infeasible basic solution that satisfies the optimality conditions, and maintains optimality through each iteration but reduces infeasibility.

The dual algorithm is critical in post-optimality sensitivity and ranging analysis and in applications such as integer programming, where an optimal LP solution is used to create one or more related problems for which that solution is infeasible (by branching or by adding cutting planes). In these situations, the related problem is generally optimized starting from that now infeasible, but still optimal, solution.

In addition, the dual simplex method often takes fewer iterations and may be less susceptible to stalling due to degeneracy than the primal algorithm. Even for solving general LPs from scratch, the dual steepest edge algorithm is generally the most efficient simplex method (though that depends on problem characteristics) [7].

The Dual LP

The dual of LP (2) is

$$\begin{aligned} &\text{maximize} && \mathbf{b}^T \mathbf{y} - \mathbf{l}^T \mathbf{w} + \mathbf{u}^T \mathbf{z} \\ &\text{subject to} && \mathbf{A}^T \mathbf{y} - \mathbf{w} + \mathbf{z} = \mathbf{c}, \\ &&& \mathbf{w} \geq \mathbf{0}, \mathbf{z} \geq \mathbf{0}. \end{aligned} \quad (14)$$

In addition, if $l_j = -\infty$ then $w_j = 0$ and if $u_j = \infty$ then $z_j = 0$. Applying complementary slackness, one can derive a one-to-one correspondence between the bases for Equations (2) and (14). Consider the basis described in

Equation (3). In dual form:

$$\begin{aligned}
& \text{maximize} \\
& \mathbf{b}^T \mathbf{y} - \mathbf{l}_B^T \mathbf{w}_B - \mathbf{l}_L^T \mathbf{w}_L - \mathbf{l}_U^T \mathbf{w}_U - \mathbf{l}_F^T \mathbf{w}_F \\
& + \mathbf{u}_B^T \mathbf{z}_B + \mathbf{u}_L^T \mathbf{z}_L + \mathbf{u}_U^T \mathbf{z}_U + \mathbf{u}_F^T \mathbf{z}_F, \\
& B^T \mathbf{y} - \mathbf{w}_B + \mathbf{z}_B = \mathbf{c}_B, \\
& L^T \mathbf{y} - \mathbf{w}_L + \mathbf{z}_L = \mathbf{c}_L, \\
& U^T \mathbf{y} - \mathbf{w}_U + \mathbf{z}_U = \mathbf{c}_U, \\
& F^T \mathbf{y} - \mathbf{w}_F + \mathbf{z}_F = \mathbf{c}_F, \\
& \mathbf{w}_B \geq \mathbf{0}, \mathbf{w}_L \geq \mathbf{0}, \mathbf{w}_U \geq \mathbf{0}, \mathbf{w}_F \geq \mathbf{0}, \\
& \mathbf{z}_B \geq \mathbf{0}, \mathbf{z}_L \geq \mathbf{0}, \mathbf{z}_U \geq \mathbf{0}, \mathbf{z}_F \geq \mathbf{0}.
\end{aligned} \tag{15}$$

Then the complementary dual basic solution to Equations (4)–(11) meets the following criteria:

- $\mathbf{y}$ is basic, $\mathbf{w}_B$ and $\mathbf{z}_B$ are not. So $\mathbf{y} = B^{-T} \mathbf{c}_B$.
- $\mathbf{w}_L, \mathbf{z}_U$ are always basic, $\mathbf{w}_U$ and $\mathbf{z}_L$ are not. So $\mathbf{w}_L = L^T \mathbf{y} - \mathbf{c}_L$ and $\mathbf{z}_U = \mathbf{c}_U - U^T \mathbf{y}$.
- If $(F^T \mathbf{y})_\phi \geq (\mathbf{c}_F)_\phi$ then $(\mathbf{w}_F)_\phi$ is basic and $(\mathbf{w}_F)_\phi = (F^T \mathbf{y} - \mathbf{c}_F)_\phi$, otherwise $(\mathbf{z}_F)_\phi$ is basic and $(\mathbf{z}_F)_\phi = (\mathbf{c}_F - F^T \mathbf{y})_\phi$.

This solution is dual feasible if and only if the optimality conditions from the primal bounded-variable simplex method are satisfied. A primal-dual complementary basic pair where both solutions are feasible is optimal for both problems.

The w_j and z_j associated with infinite lower and upper bounds, respectively, can be considered as artificial variables and given dual objective coefficients of zero. This is irrelevant for variables with one infinite bound, as the dual slack corresponding to the infinite bound is never basic. For free variables, any feasible dual solution will have both dual slacks equal to zero. For dual solutions that violate this condition, setting the dual objective coefficient to zero gives the same objective value for both complementary solutions.

The Bounded-Variable Dual Simplex Method

For simplicity, assume that $\mathbf{l}$ and $\mathbf{u}$ are finite (so $\mathcal{F} = \emptyset$) and $\mathbf{l} < \mathbf{u}$.

The dual simplex method works with the primal basic form of Equation (3), but begins with a dual-feasible basis. If the corresponding primal solution is infeasible, then an infeasible leaving variable is selected. A ratio test is performed to find an entering variable that preserves dual feasibility. Then the standard pivot step is performed. The algorithm terminates when optimality or dual unboundedness (primal infeasibility) is detected.

1. *Initialization.* Identify a dual BFS (see the section titled “Dual Phase I”). Factor B , solve $B\mathbf{x}_B = \mathbf{b} - L\mathbf{l}_L - U\mathbf{u}_U$, and solve $B^T \mathbf{y} = \mathbf{c}_B$ (see the section titled “Basis Factorization”). Compute $\bar{\mathbf{c}}_N = \mathbf{c}_N - N^T \mathbf{y}$.
2. *Dual optimality test/leaving variable.* If $\mathbf{l}_B \leq \mathbf{x}_B \leq \mathbf{u}_B$, then *stop* (the current dual BFS is primal feasible/dual optimal). Otherwise, select an index $i^* \in \mathcal{B}$ such that $x_{i^*} < l_{i^*}$ or $x_{i^*} > u_{i^*}$ (see the section titled “Dual Steepest Edge Pricing”).
3. *Direction/ratio test/entering variable.* Solve $B^T \mathbf{v} = \mathbf{e}^{\beta(i^*)}$ (where $\mathbf{e}^{\beta(i^*)}$ is the unit vector with 1 in the position in $\mathcal{B}$ of the index i^*). Compute $\mathbf{q}_L = L^T \mathbf{v}$, $\mathbf{q}_U = U^T \mathbf{v}$.
 - If $x_{i^*} < l_{i^*}$, let $\bar{\mathcal{L}} = \{j \in \mathcal{L} : q_j < 0\}$, $\bar{\mathcal{U}} = \{j \in \mathcal{U} : q_j > 0\}$.
 - If $x_{i^*} > u_{i^*}$, let $\bar{\mathcal{L}} = \{j \in \mathcal{L} : q_j > 0\}$, $\bar{\mathcal{U}} = \{j \in \mathcal{U} : q_j < 0\}$.
 If $\bar{\mathcal{L}} = \bar{\mathcal{U}} = \emptyset$ then *stop* (the dual is unbounded and the primal is infeasible). Otherwise, let $j^* = \arg \min_{j \in \bar{\mathcal{L}} \cup \bar{\mathcal{U}}} |\bar{c}_j / q_j|$. Solve $B\mathbf{d} = \mathbf{A}_{j^*}$. Let

$$\gamma^* = \begin{cases} (x_{i^*} - l_{i^*}) / q_{j^*} & \text{if } x_{i^*} < l_{i^*}, \\ (x_{i^*} - u_{i^*}) / q_{j^*} & \text{if } x_{i^*} > u_{i^*}. \end{cases}$$

4. *Pivot and update.*
 - (a) Set $\mathbf{x}_B := \mathbf{x}_B - \gamma^* \mathbf{d}$.
 - (b) • Add i^* to $\mathcal{L}$ if $x_{i^*} = l_{i^*}$ or to $\mathcal{U}$ if $x_{i^*} = u_{i^*}$, and set the $\beta(i^*)$ entry of $\mathcal{B}$ to j^* .
 - $x_{j^*} := x_{j^*} + \gamma^*$.
 - (c) Set $\bar{c}_{i^*} := -\bar{c}_{j^*} / q_{j^*}$, $\bar{c}_j := \bar{c}_j + \bar{c}_{i^*} q_j$, for $j \in \mathcal{L} \cup \mathcal{U}$.
 - (d) Set $\mathbf{y} := \mathbf{y} + \tau^* B_{\beta^*}^{-T}$, where $\tau^* = \bar{c}_{j^*} / (\mathbf{d}_B)_{\beta^*}$.

- (e) Set $\zeta := \zeta + \gamma^* \bar{c}_j^*$.
- (f) Replace B_{β^*} with A_{j^*} and update the factorization of B .
- (g) Go to Step 2.

In the case where some bounds are infinite, the corresponding dual slacks do not appear in the problem. This situation leads to a rather straightforward extension to the algorithm, but it adds significant complexity to the bookkeeping.

Dual Phase I

In many contexts (such as post-optimality analysis and integer programming), a problem with a known optimal basis is modified, and a primal-optimal (hence dual-feasible) basis for the modified problem can be easily constructed from the optimal basis for the unmodified problem. But for solving problems from scratch using dual simplex, it is necessary to construct a dual-feasible basis directly.

If all l_j and u_j are finite, there is an easy dual-feasible basis:

- Let B be the all-slack basis, so $y = c_B = 0$.
- For the remaining variables, let $j \in \mathcal{L}$ if $c_j \geq 0$, $j \in \mathcal{U}$ if $c_j < 0$.

If there is no obvious dual-feasible basis, then a dual phase I procedure must be implemented.

As with primal phase I, there are many possible variations involving changing objective function coefficients so that the starting basis is dual feasible and changing bounds to make dual feasibility for the original objective correspond to optimality for the phase I problem.

Dual Steepest Edge Pricing

The reduced costs for the dual problem are given by the values of the primal variables; basic variables that violate their bounds are candidates to leave the primal basis. Analogs of exact and approximate steepest edge pricing rules, in which the true dual ascent rates are computed instead of the ascent rates per unit change in the pivot variable, can

be derived for the dual simplex method as well [14]. To make these methods efficient, analogs of the update methods for steepest edge pricing are also necessary.

SPARSITY AND LINEAR ALGEBRA

The main expense of a simplex iteration is the requirement to solve systems of equations involving the basis matrix B . Because LPs in practice are generally extremely sparse (only a small fraction of entries in A are nonzero), implementation of solution techniques specialized for sparse, asymmetric systems is critical for good performance. It is also critical to update solutions and factorizations from iteration to iteration, rather than to re-solve from scratch.

Data Structures

Rather than store all entries in a sparse vector or matrix, it is usually advantageous with respect to both memory and running time to store only the nonzero entries and their locations. Consider the following example matrix (blanks represent zero entries):

$$A = \begin{bmatrix} 5 & 3 & & 4 & & \\ & -1 & 2 & & 1 & \\ & 3 & 3 & -1 & & \\ 1 & & & 1 & & \end{bmatrix}$$

If rows are indexed from 0 to 3 and columns from 0 to 5 (the common array indexing rule for most modern programming languages), A can be represented in column-major form using the following data structure:

cstart	0	2	5	6	8	10	11				
rindex	0	3	0	1	2	2	1	3	0	2	1
value	5	1	3	-1	3	3	2	1	4	-1	1

Here, $cstart[j]$ is the index in the other two arrays of the first entry in column j , and $cstart[n]$ is the index of the entry after the last one in the other two arrays, that is, the number of nonzeros in the

matrix. Thus, the nonzeros in column j of A are described in `rindex[cstart[j]]` through `rindex[cstart[j+1]]-1`, which contain the row indices of nonzeros in column j , and `value[cstart[j]]` through `value[cstart[j+1]]-1`, which contain the values of those entries. A similar data structure can hold the matrix entries in row-major order. Each can be constructed from the other in time linear in the number of nonzeros.

Matrix-vector multiplication ($\mathbf{y} = A\mathbf{x}$) can be carried out efficiently if A is stored in column-major order by computing a dense linear combination of columns ($\mathbf{y} = \sum_{j \in \mathcal{J}} x_j A_j$) and collecting the nonzeros in $\mathbf{y}$. If A is stored in row-major order, then inner products of $\mathbf{x}$ and rows of A can be computed efficiently by forming a dense copy of $\mathbf{x}$ and summing the pairwise products over the nonzeros in each row A_i .

A modification to this structure supports the inclusion of some buffer entries in each column so that rows can be added efficiently. The modification introduces an additional `cend` array that points to the first unused entry in each block of column entries. Obviously, an analogous structure can be used to store the matrix in row-major order.

Basis Factorization

Rather than computing B^{-1} explicitly to solve $B\mathbf{x} = \mathbf{b}$, it is preferable for both accuracy and efficiency to factor B into the product of triangular matrices, $PB = LU$, where P is a permutation matrix (permutation of the rows of the identity matrix), L is unit lower triangular, and U is upper triangular. The solution is computed by solving $L\mathbf{v} = P\mathbf{b}$ by forward substitution and then solving $U\mathbf{x} = \mathbf{v}$ by back substitution.

For “right-hand” systems, $\mathbf{y}^T B = \mathbf{c}^T$, the procedure is to solve $U^T \mathbf{w} = \mathbf{c}$ by forward substitution, then solve $L^T \mathbf{v} = \mathbf{w}$ by back substitution, and finally compute $\mathbf{y} = P^T \mathbf{v}$.

The factorization $PB = LU$ is computed using a variation of Gaussian elimination. The primary operation in Gaussian elimination is the addition of a multiple of one row to another, with the goal of zeroing a particular entry in the target row. It is possible that a row update operation introduces

a nonzero value into an entry that was previously zero. Such an entry is called *fill-in*. The two conflicting goals in selecting the sequence of operations for initial factorization are to minimize fill-in and to minimize the error in the computation of the solution.

Rudimentary LU Factorization. In Gaussian elimination, the subdiagonal elements of each column in turn are zeroed out by first swapping a pair of rows on and below the diagonal (if necessary) to place a nonzero element on the diagonal (the pivot), then adding multiples of the pivot row to the rows below to zero the entries in the pivot column. The same updates are applied to the right-hand side. The resulting system $U\mathbf{x} = \bar{\mathbf{b}}$ is solved by back substitution. It is apparent that $U = L^{-1}PB$ and $\bar{\mathbf{b}} = L^{-1}P\mathbf{b}$ for an appropriate permutation matrix P (representing the collected row interchanges) and lower-triangular matrix L^{-1} (representing the elimination steps).

In LU factorization, the row interchanges and the inverses of the row updates are recorded in P and L . The right-hand side is not updated—instead, the solution is computed with two triangular solves, as described above.

Numerical stability of Gaussian elimination is achieved by avoiding small pivot elements. The most common implementation for dense matrices utilizes *partial pivoting*: selecting the largest magnitude element on or below the diagonal in the pivot column to use as the pivot element.

The problem of choosing a pivot sequence that minimizes fill-in is NP -complete. The best-known heuristic technique for avoiding fill-in is from Markowitz [22]. Suppose we are pivoting in row k and column k . Let p_i^k be the number of nonzeros in row i in column k or greater, and q_j^k be the number of nonzeros in column j in row k or greater. Then Markowitz proposes selecting a pivot element in row i' and j' that minimizes $(p_{i'}^k - 1)(q_{j'}^k - 1)$.

The Factorization of Suhl and Suhl. There are any number of strategies for making the trade-off between numerical stability and sparsity. A particularly effective strategy for the simplex method is that of Suhl and

Suhl [23]. This method first selects pivots from singleton columns, then singleton rows. It then searches rows and columns with small numbers of nonzeros for a pivot that exceeds a dynamically adjusted threshold. If none is found, denser rows and columns are searched. If the search fails to find a suitable pivot, the factorization fails. As the factors are computed, entries below a cutoff value are set to zero.

Basis Update

Refactoring the basis matrix B from scratch at each simplex iteration would be prohibitively expensive. Fortunately, the change in B at each iteration is restricted to a single column, so that the factorization can be updated efficiently. There are two main strategies for carrying out the updates: product-form updates and rank-one updates.

The Basic Product-Form Update. The standard simplex pivot is based on an update that constructs a matrix E_k such that $B_{k+1}^{-1} = E_k^{-1}B_k^{-1}$. Pre-multiplication of $B_k^{-1}[A \ b]$ by E_k^{-1} achieves the effect of pivoting in the tableau simplex method (except for the objective row update). Recall from Equation (12) that E_k is an eta matrix, which differs from the identity matrix in exactly one column—in our case, in column β^* , corresponding to the leaving variable. That column is $\pm \mathbf{d}_B$, as computed in Step 2 of the algorithm in the section titled “Bounded-Variable Simplex Method.” The inverse of E_k is the eta matrix given in Equation (13).

Instead of actually multiplying out $E_k^{-1}B_k^{-1}$, the *product form of the inverse* simply keeps a list of the eta matrices from iteration to iteration: $B_k^{-1} = E_{k-1}^{-1}E_{k-2}^{-1}\dots E_0^{-1}B_0^{-1}$. Then $\mathbf{x} = B_k^{-1}\mathbf{b}$ is computed by pre-multiplying $\mathbf{b}$ by B_0^{-1} and then iteratively by $E_0^{-1}, E_1^{-1}, \dots, E_{k-1}^{-1}$. This procedure is often referred to as *ftran* or *forward transformation*. To compute $\mathbf{y} = B^{-T}\mathbf{c}$, pre-multiply $\mathbf{c}$ iteratively by $E_{k-1}^{-T}, E_{k-2}^{-T}, \dots, E_0^{-T}$ and then by B_0^{-T} . This procedure is known as *btran*, or *backward transformation*.

As noted in the section titled “Basis Factorization,” it is not desirable to maintain explicit inverses. Instead, the *product form of*

the basis factors keeps the *LU*-factorization of B_0 and a list of uninverted eta matrices: $L_0U_0E_0E_1\dots E_{k-1}\mathbf{x} = P_0\mathbf{b}$. This system can be solved using the following *ftran*: solve $L_0\mathbf{w} = P_0\mathbf{b}$ and $U\mathbf{v}_0 = \mathbf{w}$, then iteratively solve $E_0\mathbf{v}_1 = \mathbf{v}_0$, $E_1\mathbf{v}_2 = \mathbf{v}_1, \dots, E_k\mathbf{v}_{k+1} = \mathbf{v}_k$. Then $\mathbf{x} = \mathbf{v}_{k+1}$. Right-hand systems $E_{k-1}^TE_{k-2}^T\dots E_1^TU_0^TL_0^TP_0\mathbf{y} = \mathbf{c}$ can be solved by the following *btran*: let $\mathbf{v}_0 = \mathbf{c}$, iteratively solve $E_1^T\mathbf{v}_1 = \mathbf{v}_0$, $E_2^T\mathbf{v}_2 = \mathbf{v}_1, \dots, E_k^T\mathbf{v}_k = \mathbf{v}_{k-1}$, then solve $U_0^T\mathbf{w}_1 = \mathbf{v}_k$, $L_0^T\mathbf{w}_2 = \mathbf{w}_1$, and compute $\mathbf{y} = P^T\mathbf{w}_2$.

A difficulty with the product-form update is that the pivot element is dictated by the choice of entering and leaving variables. If the pivot is small, then numerical difficulties can result. Also, there is limited opportunity to control sparsity. A more effective update would give the implementation some control over stability and sparsity.

Rank-One Updates. Any matrix of rank one can be written as $\mathbf{p}\mathbf{q}^T$ where $\mathbf{p}$ and $\mathbf{q}$ are vectors. A rank-one update of B_k to produce B_{k+1} is accomplished by computing the product of B_k and E_k defined in Equation (12), first distributing B_k over the terms in the sum:

$$\begin{aligned} B_k E_k &= B_k \left(I - (\mathbf{d}_B^k + \mathbf{e}^{\beta^*}) (\mathbf{e}^{\beta^*})^T \right) \\ &= B_k - (B_k \mathbf{d}_B^k + B_k \mathbf{e}^{\beta^*}) (\mathbf{e}^{\beta^*})^T \\ &= B_k + (A_{j^*} - (B_k)_{\cdot\beta^*}) (\mathbf{e}^{\beta^*})^T. \end{aligned}$$

Ignoring row permutations for now, if $B_k = LU$, then $L^{-1}B_{k+1} = U + (L^{-1}A_{j^*} - U_{\cdot\beta^*}) (\mathbf{e}^{\beta^*})^T$. This matrix is not upper triangular, however—the new column represents a *spike* that extends below the diagonal:

$$\begin{bmatrix} * & * & * & * & * & * & * \\ & * & * & * & * & * & * \\ & & + & - & - & - & - \\ & & | & * & * & * & * \\ & & | & & * & * & * \\ & & | & & & * & * \\ & & & & & & * \end{bmatrix}.$$

There are several techniques for restoring the upper-triangular structure of U . The Bartels-Golub [24], Forrest-Tomlin [25], and Saunders [26] methods all proceed by permuting

the spike to the last column (shifting intervening columns to the left), and then permuting the pivot row to the bottom of the matrix (shifting lower rows up):

$$\begin{bmatrix} * & * & * & * & * & * & * \\ & * & * & * & * & * & * \\ & & * & * & * & * & | \\ & & & * & * & * & | \\ & & & & * & * & | \\ & & & & & * & | \\ & - & - & - & - & + & \end{bmatrix}.$$

Reid [27] shifts the spike to the left only as far as necessary:

$$\begin{bmatrix} * & * & * & * & * & * & * \\ & * & * & * & * & * & * \\ & & * & * & * & | & * \\ & & & * & * & | & * \\ & & & & * & | & * \\ & - & - & - & + & - & * \end{bmatrix}.$$

The methods then differ in how they perform the elimination of the spike row. Bartels-Golub performs partial pivoting. The others take steps to limit fill-in. In these methods, fill-in is restricted to the L matrix.

Suhl and Suhl [28] shift the spike column to the left as far as necessary to make the resulting matrix upper Hessenberg; that is, upper triangular except for possible nonzeros in the first subdiagonal:

$$\begin{bmatrix} * & * & * & * & * & * & * \\ & * & * & * & * & * & * \\ & & - & - & - & + & - \\ & & * & * & * & | & * \\ & & & * & * & | & * \\ & & & & * & | & * \\ & & & & & & * \end{bmatrix}.$$

The rows below the pivot row are used to eliminate the pivot row entries to the left of the relocated spike:

$$\begin{bmatrix} * & * & * & * & * & * & * \\ & * & * & * & * & * & * \\ & & & & & + & - \\ & & * & * & * & | & * \\ & & & * & * & | & * \\ & & & & * & | & * \\ & & & & & & * \end{bmatrix}.$$

Then the pivot row is shifted down to restore the upper triangular structure:

$$\begin{bmatrix} * & * & * & * & * & * & * \\ & * & * & * & * & * & * \\ & & * & * & * & | & * \\ & & & * & * & | & * \\ & & & & * & | & * \\ & & & & & + & - \\ & & & & & & * \end{bmatrix}.$$

Pivots are stored in L , which is kept as a collection of column and row eta matrices.

Again, the details of implementing this procedure efficiently are too involved to present here, but they can be found in Ref. 8.

Other Sparse Operations

Various steps in the algorithm require operations with vectors and matrices. Depending on the nature of the operations and on the problem characteristics, it may be possible to exploit vector sparsity in the various solves and updates. The detailed algorithms need to be analyzed to see where sparsity can be exploited.

CONTROLLING ROUND-OFF ERRORS

Tolerances

Most present-day floating-point implementations are based on the IEEE-754 standard. An excellent introduction to floating-point arithmetic is Ref. 29.

The representation of floating-point numbers in computers is of limited precision. This means that the arithmetic on those quantities is subject to rounding errors. Over the course of a sequence of several such operations, these errors can accumulate enough to render the final result significantly inaccurate or even meaningless. In addition, comparisons of the results of such computations to other results or to fixed values must allow for small errors. The selection of tolerances for such comparisons and for accuracy tests is critical to the reliability of a simplex method implementation. It is also something of an art.

The need for tolerances in the simplex method arises at several points in the algorithm:

- *Optimality test/entering variable.* Is $\bar{c}_j$ for $j \in \mathcal{N}$ significantly different from zero?
- *Direction/ratio test/leaving variable.* Is a basic variable close to or outside one of its bounds? Is a candidate pivot element too close to zero? Is there more than one candidate for leaving variable?
- *Pivot and update.* Has the factorization or basis update resulted in a fortuitous cancellation? Are the current factorizations and solutions accurate enough; that is, are $Bx_B = \hat{b} = b - Nx_N$ and $B^T y = c_B$?

For example, for standard double-precision arithmetic with 15-digit precision, Murtagh [30] suggests values of 10^{-5} for the optimality tolerance, 10^{-8} for pivot rejection, and 10^{-6} for the tolerance on $\|\hat{b} - Bx_B\|_\infty$. Murtagh also suggests 10^{-10} for annihilating a matrix coefficient, but the Suhl and Suhl factorization and update described in the sections titled “Basis Factorization” and “Basis Update” use a dynamic annihilation tolerance.

The use of tolerances in determining the leaving variable is somewhat more complex. For feasibility, Maros [8] suggests a tolerance in the range $10^{-8} \leq \epsilon_f \leq 10^{-6}$. This value is used in the computation of β^* to find the distances for each basic variable to slightly relaxed lower or upper bounds.

Harris [15] proposes a technique for applying this relaxed ratio to improve numerical stability. Her idea is to use the minimum relaxed ratio as a bound on acceptable exact ratios, and to choose the numerically most attractive pivot from among candidate variables with an exact ratio smaller than this bound. Note that this method allows the solution to take on small infeasibilities (on the order of ϵ_f), which must eventually be eliminated. Some of the anti-degeneracy techniques mentioned in the section titled “Degeneracy” (notably the EXPAND procedure [21]) are designed to overcome this difficulty.

Refactoring

As updates accumulate over several iterations, the accuracy of `ftran` and `btran`—as well as x_B , y , and any other updated values—deteriorates and the cost of carrying them out increases. When the accuracy gets too low or the cost gets too high, the updates must be discarded. The basis matrix is then refactored from scratch, and the primal and dual solutions are recomputed using the fresh factorization. Product-form updates require refactorization after 30–50 pivots. The triangular updates reduce the frequency of refactorization to every 100–150 iterations.

Scaling

One source of numerical difficulties is a large range of coefficient values in the instance input. Model builders prefer to work in the natural units associated with the quantities they are using, but the choice of units can result in large differences in the magnitudes of coefficients.

Often, scaling the rows and columns before solving the LP can alleviate much of the resulting numerical instability. Of course, scaling columns requires unscaling the solution before reporting it. If the unscaled solution does not satisfy termination criteria for the unscaled problem, the unscaled problem is resolved starting from the scaled problem’s final basis.

Note that for standard floating-point representations on current computers, a scale factor that is a power of 2 is desirable, so that precision of the mantissa is preserved. In addition, scaling is not always advantageous in the simplex method—its usefulness depends on problem characteristics. For example, in problems with many zeros and ones, fortuitous cancellation can be exploited, but scaling may destroy that structure.

Common scaling methods include:

- *Equilibration.* In equilibration scaling, each row is scaled so that the largest element has magnitude 1; then each column is also scaled the same way. Thus, each row and column has the

maximum magnitude of any entry equal to 1.

- *Mean-Based Scaling.* Here, the geometric mean of the smallest and largest nonzero magnitudes or the arithmetic mean of nonzeros (or the nearest power of 2) is used to scale rows, then columns.
- *Curtis and Reid's Method.* Curtis and Reid [31] propose a conjugate gradient method to compute a scale factor that approximately minimizes $\sum_{i,j:a_{ij} \neq 0} \log^2 |a_{ij}|$. The method converges rapidly and generally requires negligible time compared to that required to solve the LP.

Often, the methods are used in combination and applied repeatedly some small number of times. However, a study by Elble and Sahinidis [32] indicates that equilibration scaling alone generally provides as much benefit as combined techniques.

OTHER ISSUES

Preprocessing

Often, problem size and difficulty can be reduced by preprocessing ("presolving") the problem. Brearley *et al.* [33] proposed the basic techniques for detecting redundant constraints and bounds and removing or tightening them, fixing variables, converting constraints to bounds, and converting columns to bounds on shadow prices. The procedures are applied repeatedly until no further changes are detected or for a fixed number of passes, and each transformation is recorded so that the solution to the presolved problem can be transformed to a solution to the original problem. At the end of the solution process, the changes are backed out and the solution to the original problem is verified or repaired.

Parallelism

The simplex method, with all sparsity-exploiting techniques in play, does not offer many opportunities for large-grain parallelism of the sort that is well suited for cluster computing.

There are some opportunities for exploiting more fine-grained parallelism for highly rectangular problems. The most obvious place is in pricing for problems with many variables, which can exploit multicore CPUs or symmetric multiprocessing machines with multiple CPUs accessing shared memory via a high-speed bus. Here, the relatively expensive complete pricing operation in steepest edge techniques can be farmed out across CPUs.

The ratio test is another trivially parallelizable step, but it is also cheap, so the savings from parallelizing that procedure must be traded off carefully against the cost of starting up and managing the parallel tasks.

RESOURCES

There are several books on linear programming that focus on [8,30,34] or devote significant space to [35,36] implementation issues. Of the former, Maros's book [8] is the most current and complete, describing in detail the algorithms and data structures required to implement nearly all of the techniques described here.

Maros's book does not include code, but there are several open-source or source-available codes accessible on the World Wide Web. (Proprietary codes are not described here, as they do not provide source code that could be studied to learn about implementations.)

- The COIN-OR LP solver (CLP) (<http://projects.coin-or.org/Clp/>) is an open-source C++ code written by John Forrest of IBM and others. It is the preferred LP solver for the COIN-OR Branch-and-Cut (CBC) solver (<http://projects.coin-or.org/Cbc/>), also written by Forrest.
- The Dynamic LP solver (DyLP) (<http://projects.coin-or.org/DyLP/>) is an open-source C code written by Lou Hafer of Simon Fraser University. It is the LP solver in Hafer's bonsaiG mixed integer programming (MIP) code.
- LPSolve (<http://lpsolve.sourceforge.net/>) is an open-source linear and mixed

integer programming solver written in C originally by Michel Berkelaar and currently maintained by Kjell Eikland and Peter Notebaert.

- The GNU Linear Programming Kit (GLPK) (<http://www.gnu.org/software/glpk/>) is an open-source C code for linear and MIP developed by Andrew Makhurin.
- SoPlex (<http://soplex.zib.de/>) is free for academic and nonprofit use. It is an implementation of the simplex method in C++, developed at Konrad-Zuse-Zentrum für Informationstechnik Berlin.
- Robert Vanderbei makes educational implementations of simplex and interior-point methods in C available (<http://www.orfe.princeton.edu/~rvdb/LPbook/src/>) in conjunction with his textbook [13].

IMPOSSIBILITY THEOREMS AND VOTING PARADOXES IN COLLECTIVE CHOICE THEORY

ELIZABETH MAGGIE PENN
Department of Political Science,
Washington University,
St. Louis, Missouri

In the field of positive political theory, the term *impossibility theorem* refers to a collection of results that take as given a set of normatively appealing criteria and deductively prove that such a set of criteria are inconsistent: that is, it is impossible for a voting system—any voting system—to simultaneously satisfy the given set of criteria. This approach to the study of voting systems is called *axiomatic*, because the normative criteria that we might like our voting systems to satisfy are used as starting points in these results, or taken as a given. In other words, these normative criteria are *axioms*, which in mathematics are defined as statements that are assumed solely for the sake of studying the consequences that follow from them.

The mathematical study of voting systems is motivated by the fact that any group seeking to make a collective decision must choose some method of translating the preferences of the group into a societal outcome. Moreover, there are an infinite number of such methods: from simple majority rule, to weighted voting, to choosing a “dictator” to unilaterally make societal decisions. A brief consideration of the types of voting rules that have been used throughout the course of human history reveals an assortment that varies not only with respect to procedure and formula but also with respect to the goals that each system was intended to further. In ancient Athens, for example, the election of delegates was done by lottery, and it is estimated that half of all citizens over the age of 30 served as public officers at some point in their lives. This process formed the basis of Aristotle’s concept of democracy, which espoused “ruling and being ruled by turns” [1, pp. 20–22].

Conversely, many modern elections utilize runoffs to ensure that electoral winners have received the support of a majority of voters. An advisory board may utilize weighted voting to ensure that more knowledgeable experts have more say in a final decision.

The concepts of “ruling by turns,” “winners should receive the support of a majority,” and “greater voting weight to more knowledgeable individuals” can all be thought of as decision-making desiderata of the particular groups described above. Axiomatic approaches to the study of voting systems are informative and useful because they take these types of *goals* of a voting system as a given, and focus on whether any voting system is capable of satisfying the goals and, if so, what such a voting system should look like. For example, suppose a group wishes to utilize a voting system in which no individual has an incentive to misrepresent his or her true preferences, in other words, a voting system in which all individuals are always best served by voting truthfully. The Gibbard–Satterthwaite theorem, an important impossibility theorem, would then tell us that this goal is impossible to attain with any reasonably democratic voting system.

The remainder of this article presents a brief survey of several of the most well-known impossibility theorems, including Arrow’s theorem and the Gibbard–Satterthwaite theorem mentioned above. This article also discusses various widely known *voting paradoxes*, or particular examples of how seemingly sensible voting procedures can produce undesirable outcomes. These paradoxes can be thought of as impossibility results in their own right, as they demonstrate an incompatibility between sensibility in procedure and sensibility in outcome.

NOTATION AND DEFINITIONS

The most well-known impossibility theorems in positive political theory involve voting systems, or systems of *preference aggregation*. Thus, the theorems concern

procedures that take a collection of individuals with heterogeneous preferences as an input, and produce some collective preference ordering or collective choice as an output. It should be noted, however, that there are many other impossibility theorems in positive political theory that do not explicitly involve preference aggregation, *per se*.

To present these results, some simple notation is needed. First, we assume that there exists a collection of individuals seeking to make a collective choice. This group is termed N , and it is of size n . We assume that N contains at least two individuals, or that $n \geq 2$. Second, we assume that there is a finite set of alternatives, or policies, under consideration by the group. We call this set X , and assume (to begin with) that X contains at least three different alternatives. And third, we assume that each individual has his or her own preference ordering of the alternatives under consideration. This *preference relation* is denoted $\succeq_i$ for person i . Thus, if person i likes alternative x more than alternative y , it is denoted by $x \succeq_i y$.

We assume that each individual's preference relation $\succeq_i$ is a *weak order*, which means that it is a way of comparing pairs of alternatives that is *reflexive*, *transitive*, and *complete*. The $\succeq_i$ relation is intended to be similar to $\geq$, the "greater than or equal to" relation, which we use to compare numbers on the real line. Reflexivity means that for any alternative x , it is the case that $x \succeq_i x$, or that i likes x at least as much as x . Completeness means that for any two alternatives, x and y , it is the case that either $x \succeq_i y$, or that $y \succeq_i x$, or both. In other words, i either likes x at least as much as y , or y at least as much as x , or is indifferent between the two. Last, transitivity means that if $x \succeq_i y$ and $y \succeq_i z$, then $x \succeq_i z$. This final condition is a rationality condition; voters cannot have preferences that "cycle" in the sense of ordering the alternatives $x \succ y$, $y \succ z$, and $z \succ x$.

At times we decompose $\succeq_i$ into two parts: $\succ_i$ and $\sim_i$. While $\succeq_i$ represents Person i 's preference relation, $\succ_i$ represents his *strict* preferences, and $\sim_i$ represents his *indifference*. Thus, $x \succ_i y$ implies that $x \succeq_i y$, but not $y \succeq_i x$, or that i strictly prefers x to y . Similarly, $x \sim_i y$ implies that both $x \succeq_i y$ and

that $y \succeq_i x$, or that i is indifferent between x and y . Last, we use the term ρ to describe the entire collection of individual preferences. Thus, $\rho = (\succeq_1, \succeq_2, \dots, \succeq_n)$.

More concretely, suppose we have two people in our group, $N = \{1, 2\}$, and that we have three alternatives under consideration, $X = \{x, y, z\}$. Suppose Person 1 prefers $x \succ_1 y \succ_1 z$ and Person 2 has preferences $y \succ_2 x \succ_2 z$. In other words, Person 1 strictly prefers x to y and z , and strictly prefers y to z , and Person 2 strictly prefers y to z and x , and z to x . Then

$$\rho = \begin{matrix} x \succ_1 y \succ_1 z \\ y \succ_2 z \succ_2 x \end{matrix} \quad (1)$$

Thus, ρ characterizes our group and the preferences of its members.

Now that we have described the collection of alternatives, people, and their preferences over the alternatives, we can begin to consider various ways of conceptualizing collective choice. We consider two different types of mechanisms for generating a group choice. The first is termed a *preference aggregation rule*, and is denoted f . This mechanism takes a preference profile ρ as an input, and generates a group preference relation, $\succeq$, over all alternatives. This group preference relation will be reflexive and complete, but not necessarily transitive.

As an example, suppose f is the method of Borda count (let us call it f_B), and ρ is the profile described in Equation (1). As there are three alternatives under consideration, Borda count works as follows: an alternative that a voter ranks first receives two points, an alternative he ranks second receives one point, and an alternative he ranks third receives zero points. The social ranking is then the sum of these scores across individuals. Thus, given the ρ in Equation (1), x receives two total points (two from Voter 1 and zero from Voter 2), y receives three total points (one from Voter 1 and two from Voter 2), and z receives one total point (from Voter 2). It follows that Borda count ranks the alternatives $y \succ x \succ z$, or more formally,

$$f_B(\rho) = y \succ x \succ z.$$

While a preference aggregation rule determines a social preference ordering of the

entire collection of alternatives under consideration, a *choice function*, F , takes a preference profile as an input and simply generates a single winner. We can also think of Borda count as choice function, F_B . In this case, our function would return the alternative with the highest Borda score, breaking a tie if need be. Using our profile ρ in Equation (1),

$$F_B(\rho) = y.$$

A choice function or preference aggregation rule satisfies a property termed *unrestricted domain* if its domain is the set of all possible preference profiles. In other words, unrestricted domain requires that these collective choice mechanisms be capable of yielding a social choice or a social preference relation when provided with *any* possible collection of preference orderings of the individuals; we cannot restrict the preferences that individuals may have. For the purposes of this article, we always assume that our preference aggregation rules and choice functions satisfy this property.

A SURVEY OF IMPOSSIBILITY THEOREMS IN VOTING THEORY

This section first briefly presents three impossibility theorems concerning preference aggregation rules: Arrow's theorem, May's theorem, and Sen's theorem. Arrow's theorem is the most well known of the impossibility theorems, and partially motivates the theorems that follow. Arrow lays out four simple axioms that any reasonable aggregation rule should (arguably) satisfy, and then proves that these axioms are incompatible with each other; no rule can simultaneously satisfy all four. May looks specifically at majority rule over two alternatives, and shows that it is the only voting system that can simultaneously satisfy several desirable axioms including *anonymity* and *neutrality*, the properties of treating all voters and all alternatives candidates equally. Sen demonstrates that a very minimal requirement that a voting rule be responsive to the preferences of more than one individual is incompatible with that rule being capable of generating a social ranking

of the alternatives that is both efficient and capable of yielding a best alternative.

This section concludes with a discussion of the Gibbard–Satterthwaite theorem, an impossibility theorem concerning choice functions. Loosely speaking, this theorem tells us that it is impossible to design a system for generating a collective choice that both takes the preferences of more than one individual into account and provides no incentive for individuals to misrepresent their preferences.

Arrow's Theorem

We begin by laying out Arrow's four axioms, or conditions that any reasonable aggregation rule should satisfy. Perhaps one of the least demanding requirements a group would seek to impose on its voting system is that a group decision is minimally responsive to the preferences of the members of that group. To this end, Arrow first defines the condition of *Pareto efficiency*.

An aggregation rule f is *Pareto efficient* if, for any profile ρ , if $x \succ_i y$ for all individuals i in N , then $x \succ y$. In words, this condition says that if *every* individual i strictly prefers x to y , then our aggregation rule f should generate a collective ranking of the alternatives that ranks x strictly higher than y . This condition rules out aggregation rules that, for example, always rank $x \succ y$, regardless of the group's x, y preferences.

Second, we might want our voting system to not consider “irrelevant” alternatives when generating a social ranking between two alternatives. In other words, the group members' preferences between alternatives c and d should not affect the social ranking of two different alternatives, a and b . This leads to Arrow's second condition of *independence of irrelevant alternatives*.

An aggregation rule f is *independent of irrelevant alternatives* (IIA) if for any two profiles, ρ and ρ' , if every individual's x, y ranking under ρ agrees with their x, y ranking under ρ' , then the social x, y ranking generated by $f(\rho)$ should agree with the social x, y ranking generated by $f(\rho')$. The example below is intended to make this concept more concrete, and to illustrate why the Borda

count procedure violates IIA. Consider the following two profiles, ρ and ρ' :

$$\rho = \begin{matrix} x \succ_1 y \succ_1 z \\ y \succ_2 z \succ_2 x \end{matrix}, \quad \rho' = \begin{matrix} x \succ_1 z \succ_1 y \\ y \succ_2 x \succ_2 z \end{matrix}. \quad (2)$$

As discussed earlier, Borda count produces the social ranking $y \succ x \succ z$ when applied to profile ρ . However, at profile ρ' , $f_B(\rho')$ generates the social ranking $x \succ y \succ z$, because at this profile x receives three combined points, y receives two, and z receives one. If we look solely at the two individuals' x, y rankings, these two profiles look identical: Voter 1 prefers $x \succ_1 y$ under both ρ and ρ' , and Voter 2 prefers $y \succ_2 x$ under both ρ and ρ' . However, $f_B(\rho)$ generates $y \succ x$, while $f_B(\rho')$ generates $x \succ y$. This is a violation of IIA.

Arrow's third axiom concerns the ability of a preference aggregation rule to generate an unambiguous winner, or a collection of winners, if there is a tie. A procedure that, for example, generates the social ranking $x \succ y$, $y \succ z$, and $z \succ x$ might not be particularly useful to a group seeking to make a collective choice, because it does not generate an unambiguously "best" collection of alternatives. Any given alternative is strictly worse than another. This leads to Arrow's third condition of *transitivity*.

An aggregation rule f is *transitive* if it always produces a transitive ordering of the alternatives. Thus, if f produces an ordering in which $x \succeq y$ and $y \succeq z$, then it must also be the case that $x \succeq z$. This condition guarantees that the social ordering generated by f cannot cycle, in the sense that it cannot produce a ranking in which $x \succ y$, $y \succ z$, and $z \succ x$; it guarantees that the social preference ordering satisfies the same rationality condition as the individual preference orderings that it was constructed from. Moreover, it ensures the existence of an alternative or collection of alternatives that are not strictly worse than anything else.

Last, Arrow's axiom of *no dictator* concerns the responsiveness of the preference aggregation rule to the preferences of more than one individual. An aggregation rule is *dictatorial* if there is one particular voter

whose individual preferences always determine the social preference ordering, irrespective of the preferences of the other voters. Formally, this condition says that there exists one voter i , so that every time $x \succ_i y$, the aggregation rule f produces the ranking $x \succ y$. An aggregation rule f satisfies *no dictator* if it is not dictatorial. We are now ready to state Arrow's theorem.

Theorem 1 [Arrow, 1950 and 1963]. *With three or more alternatives, any aggregation rule satisfying unrestricted domain, Pareto efficiency, IIA, and transitivity is dictatorial.*

Arrow's theorem then tells us that if a group wishes to design a preference aggregation rule that is Pareto efficient, transitive, and independent of irrelevant alternatives, and if we place no restrictions on the preferences that individuals may have, then the rule must grant all decision-making authority to a single individual [2,3]. Thus, any aggregation rule that satisfies no dictator *must* violate either transitivity, or Pareto efficiency, or IIA. And practically speaking, it will violate either transitivity or IIA, as the only nondictatorial aggregation rules that are ruled out by the addition of Pareto efficiency are those rules that are either null (generate a tie over all alternatives) or inverse dictatorships. This extension of Arrow's theorem to non-Pareto efficient rules was proved by Wilson [4], and is known as *Wilson's impossibility theorem*.

May's Theorem

May's Theorem comes as a response to the axiom of independence of irrelevant alternatives utilized by Arrow, which requires that group choices between pairs of alternatives depend only on individual preferences over those pairs. May argues that this condition implies that knowing a group's choice between every pair of alternatives is akin to knowing the group's entire preference relation; in this sense, Arrow's result can be thought of as a problem concerning choice over pairs. Thus, while Arrow's Theorem requires at least three alternatives in the group's choice set, May focuses solely on the

case in which there are only two alternatives under consideration.

May lays out three axioms that any preference aggregation rule should satisfy when there are two alternatives under consideration. His first condition is *anonymity*, which states that the preference aggregation rule f should treat every voter equally. This means that in $f(\succeq_1, \succeq_2, \dots, \succeq_n)$ any two arguments (e.g., $\succeq_5$ and $\succeq_3$) could be interchanged without changing the group preference relation produced by f . In other words, changing the voters' names (as defined by the subscripts on $\succeq_i$) can have no effect on how f ranks the alternatives.

May's second condition is *neutrality*, which says that the aggregation rule f does not favor either alternative. In other words, the labeling of the alternatives cannot matter to f . May's final condition is *positive responsiveness*, which says that the group preference relation should respond to individual preferences in a positive way. Thus, if we have a preference profile ρ in which $f(\rho)$ generates $x \succeq y$, then changing a single individual's preferences such that he is *more* favorable to x (i.e., changing his preferences from $y \succ_i x$ to $x \succeq_i y$, or from $x \sim_i y$ to $x \succ_i y$) should make the group strictly favor x over y (i.e., change the group preference from $x \sim y$ to $x \succ y$, or keep the group at $x \succ y$ if that was the group's ordering before i 's preferences changed).

Last, define the *method of majority rule* to be a preference aggregation rule, f_M over a pair of alternatives, x and y , in which $x \succ y$ if more people strictly prefer x to y than y to x , and $y \succ x$ if more people strictly prefer y to x than x to y , and $x \sim y$ if the same number of people prefer x to y as prefer y to x . We are now ready to state May's theorem.

Theorem 2 [May, 1952]. *The only preference aggregation rule that is anonymous, neutral, and positively responsive is the method of majority rule.*

A particularly succinct explanation of May's theorem is provided by May himself: "In Arrow's terms our theorem may be expressed by saying that any [preference aggregation rule] that is not based on simple majority decision, i.e., does not decide

between any pair of alternatives by majority vote, will either ... favor one individual over another, favor one alternative over the other, or fail to respond positively to individual preferences." [5, p. 683].

Sen's Theorem (the Liberal Paradox)

Like May's theorem, Sen's theorem can also be viewed as building upon Arrow's results. Sen argues that certain kinds of choices are personal, and that individuals should have the freedom to make these kinds of choices for themselves. In this vein, Sen defines an axiom termed *minimal liberalism*, which states that there are at least two individuals and two pairs of distinct alternatives (x, y) and (w, z) such that Person 1 is free to decide between (x, y) and Person 2 is free to decide between (w, z) . Minimal liberalism is a particular version of Arrow's condition of no dictator, as it characterizes a situation in which decision-making power is minimally decentralized. Sen shows that even a weak condition such as minimal liberalism is incompatible with a procedure that is capable of both generating transitive outcomes and being Pareto efficient.

Theorem 3 [Sen, 1970]. *No aggregation rule that produces transitive outcomes can simultaneously satisfy unrestricted domain, Pareto efficiency, and minimal liberalism.*

Sen provides the following illustration of his theorem. Consider a social choice over three alternatives: either Mr A can read a copy of *Lady Chatterly's Lover* (alternative a), or Mr B can read it (alternative b), or neither of them can read it (alternative c). Mr A, the prude, prefers neither of them reading it to himself reading it (in order to protect the impressionable Mr B), to Mr B reading it. Thus he prefers $c \succ_A a \succ_A b$. Mr B, the lascivious, prefers Mr A reads it (in order for Mr A to be exposed to Lawrence's prose), to himself reading it, to neither of them reading it, and thus prefers $a \succ_B b \succ_B c$.

An argument can be made that Mr. A should decide between the (a, c) states of the world, the states in which only he reads the book or neither reads the book. Similarly,

Mr. B should decide between the (b, c) states of the world. Thus, the condition of minimal liberalism is satisfied, and yields the social ordering $b \succ c$ (by Mr. B's preferences), and $c \succ a$ (by Mr. A's preferences). However, both individuals prefer a to b , and so Pareto efficiency along with minimal liberalism yields the cycle $a \succ b, b \succ c$, and $c \succ a$. Thus, the procedure is incapable of generating an optimal choice [6, pp. 80–81].

The Gibbard–Satterthwaite Theorem

Our final impossibility theorem, proved independently by Gibbard [7] and Satterthwaite [8], differs from the previous theorems in several important ways. First, it concerns choice functions rather than preference aggregation rules (i.e., voting systems that produce a single winner, as opposed to a social ordering of the alternatives), and second, it does not assume that a voting system takes a “true” collection of preferences as an input. Rather, it considers voting systems that take individuals' reported preferences, or ballots, as an input.

Gibbard and Satterthwaite are concerned with the *strategy-proofness* of a choice function, or the ability of a choice function to discourage insincere behavior by a voter. Suppose that $\rho = (\succeq_1, \dots, \succeq_n)$ is a “true,” or “sincere,” preference profile, whereas $\rho' = (\succeq_1, \dots, \succeq'_i, \dots, \succeq_n)$ is a profile that only differs from ρ in that Voter i reports the “insincere” preferences $\succeq'_i$, as opposed to his true preferences $\succeq_i$. Then a choice function F is *strategy-proof* if $F(\rho')$ will never generate an outcome that Voter i strictly prefers to the outcome generated by $F(\rho)$, the outcome he would have received by sincerely reporting his preferences. Thus, F being strategy-proof implies that no voter can ever strictly benefit by claiming to have preferences that are different than what they actually are. Unfortunately, Gibbard and Satterthwaite demonstrate that strategy-proofness and Pareto efficiency are not attainable with a nondictatorial procedure. Note that the definitions of “dictator” and “Pareto efficiency” used in this theorem are modified slightly from our previous definitions to accommodate the fact that we are considering choice functions.

Theorem 4 [Gibbard, 1973; Satterthwaite 1975]. *With three or more alternatives and unrestricted domain, any choice function that is strategy-proof and Pareto efficient is dictatorial.*

The Gibbard–Satterthwaite theorem proves that the possibility of strategic voting, or voting against one's true preferences, is endemic to the vast majority of voting systems. Despite their differences, the Gibbard–Satterthwaite theorem is mathematically similar to Arrow's theorem, and it has been demonstrated that the two results can be derived from what is essentially a single proof [9]. It should also be noted that Pareto efficiency can be replaced with the far weaker condition of *nonimposition*, which states that any alternative can be achieved as a social choice, given some collection of ballots.

VOTING PARADOXES

Impossibility theorems are paradoxical, in the sense that they prove that seemingly sensible conditions are incompatible with each other. While these results are quite general, in that they typically apply to a wide range of voting systems, it is also well known that specific voting systems can suffer from specific anomalies. A *voting paradox* occurs when a particular voting system yields an end result that is highly counterintuitive. The paradoxes discussed here are well-known problems stemming from widely used voting rules, and represent only a handful of the documented paradoxes.

Condorcet's Paradox

The most famous voting paradox is known as *Condorcet's paradox*, and was introduced by Marquis de Condorcet, a French mathematician and philosopher, in his 1785 treatise *Essay on the Application of Analysis to the Probability of Majority Decision*. This paradox demonstrates that majority rule with three or more alternatives may yield intransitive outcomes. It can be summed up by the following preference profile:

$$\begin{aligned} x &>_1 y >_1 z \\ \rho = y &>_2 z >_2 x . \\ z &>_3 x >_3 y \end{aligned}$$

Given profile ρ , it is clear that a majority vote between x and y would yield the social ranking $x > y$ (by the votes of persons 1 and 3); a majority vote between y and z would yield $y > z$ (by the votes of persons 1 and 2); and that a majority vote between x and z would yield the ranking $z > x$ (by the votes of persons 2 and 3). Thus, majority voting over pairs of alternatives is not guaranteed to yield transitive outcomes when there are three or more alternatives, even when we assume that individual preferences are transitive. In this case, majority voting yields the cycle $x > y$, $y > z$, and $z > x$.

Ostrogorski's Paradox

Ostrogorski's paradox involves the role of political parties as intermediaries in the process of voting. His paradox stems from the fact that the following two procedures can yield different outcomes: (i) Each voter votes for the party whose stand is closest to his own on the most issues. The winner is the party with the most votes. (ii) On a series of issues, each voter votes for the party whose stance is closest to his own. The winner is the party that wins the most issues. The following table demonstrates this paradox [10, p. 72].

<i>Voter</i>	<i>Favorite Party on Issue 1</i>	<i>Favorite Party on Issue 2</i>	<i>Favorite Party on Issue 3</i>	<i>Party Supported</i>
1	X	Y	Y	Y
2	Y	X	Y	Y
3	Y	Y	X	Y
4	X	X	X	X
5	X	X	X	X

The above table shows that a majority of voters prefer Party Y to Party X, overall. At the same time, if we examine the table issue by issue, we can see that Party X defeats Party Y on every issue. Thus, a party winning an election (Y, in this case), could fail to represent the views of a majority on every single issue.

The Additional Support (Monotonicity) Paradox

One straightforward criterion that we might like a voting system to satisfy is that increased support for a winning candidate does not turn that candidate into a loser. It is well known, however, that many two-round voting systems do not satisfy this property, and thus suffer from the additional support, or monotonicity, paradox. The following two tables demonstrate this phenomenon in a majority runoff election, or an election in which, if no candidate receives a majority, the top two vote-getters proceed to a runoff.

<i>Number of Voters</i>	<i>Preferences</i>
6	$a > b > c$
7	$b > a > c$
8	$c > a > b$

In the above election, 11 votes are required out of 21 votes for a candidate to win. Since no candidate receives a majority, a runoff is held between b and c (the two highest vote-getters), and as the a voters prefer b to c , b wins the runoff. Now suppose that three voters switch their preferences from $c > a > b$ to $b > c > a$. This is represented in the following table:

<i>Number of Voters</i>	<i>Preferences</i>
6	$a > b > c$
10	$b > a > c$
5	$c > a > b$

In this case, a and b proceed to the runoff, where a ends up defeating b by 11 to 10. Thus, by receiving strictly greater support in the second election b changes from being a winning candidate to being a losing candidate.

The Alabama Paradox

In the United States, congressional seats are awarded to the 50 states following every decennial census. The Constitution specifies that these seats should be awarded in proportion to state populations, but does not

specify a particular formula by which the seats should be distributed. Prior to 1911, the total number of congressional seats was readjusted every 10 years to account for population growth. It was because of such a readjustment that in 1882 the *Alabama paradox* was discovered: as the total number of seats to be distributed increased, the state of Alabama ended up losing a seat. This paradox is a consequence of the particular apportionment formula being used at the time, called *Hamilton's method*, which worked as follows: First, a quota is determined to represent the ideal number of people to be represented by a single congressional seat. If 435 seats are to be distributed we would get

$$\text{Quota} = \frac{\text{Population of the United States}}{435}.$$

Second, a state's ideal number of seats is determined by dividing the state's population by this quota:

$$\begin{aligned} &\text{States ideal number of seats} \\ &= \frac{\text{Population of the state}}{\text{Quota}}. \end{aligned}$$

In general, however, a state's ideal number of seats (its entitlement) will involve a fractional part. Hamilton's method specifies that each state should be awarded the whole number portion of its entitlement, and that any remaining seats to be distributed go to the states with the largest fractional portions of their entitlements. The following tables demonstrate how Hamilton's method works, and its vulnerability to the Alabama paradox.

<i>Seat Allocations with 10 Seats to Distribute</i>			
<i>State</i>	<i>Population</i>	<i>State's Ideal # of Seats</i>	<i>Seats Awarded</i>
A	1200	4.29	4
B	1200	4.29	4
C	400	1.42	2

In the above table there was one remaining seat to distribute after the states were awarded their integer amounts. This seat

went to State C, because it had the largest fractional entitlement (0.42). The next table shows what happens when the total number of seats to be distributed increases from 10 to 11.

<i>Seat Allocations with 11 Seats to Distribute</i>			
<i>State</i>	<i>Population</i>	<i>State's Ideal # of Seats</i>	<i>Seats Awarded</i>
A	1200	4.71	5
B	1200	4.71	5
C	400	1.57	1

The above table shows that when the number of seats to be distributed is increased State C's fractional entitlement dips below those of States A and B. Thus, even though there are more seats to be awarded, State C ends up losing a seat.

FURTHER READINGS

The field of voting theory is vast and growing, with many topics for the interested reader to discover. Austen-Smith and Banks [11,12] provide an extremely thorough and technical presentation of this material. A less technical introduction to this material with many real-world applications can be found in Saari [13]. Nurmi [10] provides an excellent overview of the various voting paradoxes, and a classification of their types. Balinski and Young [14] provide a history of representation paradoxes that have occurred in the context of United States congressional apportionment. Taylor [15] focuses exclusively on the manipulability of voting systems, and in particular the Gibbard–Satterthwaite theorem and its many extensions. In addition, the interested reader will find the classic texts of Arrow, May, Sen, Gibbard, and Satterthwaite to be readable and thought provoking.

IMPROVING PACKAGING OPERATIONS IN THE PLASTICS INDUSTRY

RAJESH TYAGI
SRINIVAS BOLLAPRAGADA
GE Global Research, Niskayuna,
New York

INTRODUCTION

The plastics company in question is a multibillion dollar global materials business that manufactures a variety of plastics and specialty materials such as thermoplastics, silicones, fused quartz, and ceramics. Its customers are in a wide range of industries such as automotive, appliances, optical media, construction, aerospace, transportation, medical, computers, and sports equipment. It includes several divisions whose products differ primarily in their heat resisting and sealing properties. As such, these divisions have their own niche markets. For example, one division makes sealants for consumer and industrial use, while another division supplies plastics that are widely used in the automotive industry. This project pertains to yet another division that makes materials used in high heat applications like electronics, power tools, cellular phones, and appliances. The division manufactures over 160 million lbs of material worth \$800 million annually.

Starting in late 2001, the division began to experience a manufacturing bottleneck at the manufacturing facility. In particular, the packaging operations had become a major bottleneck, impacting the production throughput of the plant. The primary reason was that the product offerings had become very diverse over time, providing little opportunity to aggregate customer orders when creating production lots. Smaller lot sizes imply more frequent cleanups, and packaging stations were especially impacted as they service many extrusion lines (or

extruders) that convert raw plastics called *resins* into finished products in the form of plastic pellets and thus, encountered frequent lot changes. As packaging failed to keep up with production, extrusion lines had to be stopped (or blocked) to prevent overflowing storage bins. Blocked extrusion lines led to the manufacturing schedules, and therefore customer orders, being delayed past their due dates. The blocking also effectively reduced the throughput capacity of the extruder lines. Management found a temporary fix by outsourcing some of the packaging operations—material was loaded onto trucks and railcars, and transported to an outside vendor for packaging at an annual cost of \$250,000. In 2003, as the demand outlook for the products brightened with the improving economy, it was clear that the problem would only get worse unless packaging operations were improved. The management looked at various possible causes and even though they felt that packaging scheduling could be improved, they were not convinced that the improvement alone would eliminate the bottleneck. Faced with an impending increase in production, management decided that increasing packaging capacity along with reconfiguration of packaging operations—assignment of packaging stations to extrusion lines—was the safer solution. To that end, they identified four alternative configurations of linking extruders to packaging stations. As will be explained later, the manufacturing under consideration is a very complex process involving many different types of materials flowing through a number of common bins and where different materials must be kept separate and thus cannot be placed in the same bin at the same time. It soon became apparent the management needed operations research expertise and the authors were brought into the project team to provide that expertise in evaluating the alternatives.

The team's initial charter was to identify the best alternative configuration—one that would minimize blockages of the extrud-

ers while requiring the minimum increase in packaging capacity (packaging stations as well as packagers). At first, team members thought of performing some spreadsheet analysis to estimate the capacities and utilizations of the packaging stations. However, the network of capacitated containers that shared the packaging stations was too complex to estimate the number of cleanups and throughput statistics using spreadsheet capability alone. Hence, the team decided to use simulation technology for the analysis.

Using simulation models, the team determined that the existing capacity was more than sufficient for packaging the output of extruders. The team's analysis showed that the bottleneck was caused not due to insufficient capacity but due to poor scheduling. The team suggested that a scheduling system that more efficiently schedules the packaging operations would significantly reduce the packaging bottleneck. In addition, it would free up some of the packagers' time to focus on other activities. The division then funded a project to develop this packaging scheduling system. The team implemented the system in November 2003, resulting in significant benefits that included increased capacity, improved productivity, and elimination of outsourced packaging cost. These benefits are described in greater detail toward the end.

The rest of the article is organized into the following sections: (i) packaging operations (in which packaging operations are described in detail), (ii) capacity analysis (analysis of the packaging capacity using discrete event simulation) that includes a literature review, (iii) the packaging problem statement, (iv) the packaging scheduling algorithm (a novel heuristic algorithm for scheduling packaging operations), (v) system implementation and use, (vi) benefits and summary, and (vii) references.

PACKAGING OPERATIONS

The packaging system that was simulated, developed, and eventually implemented is part of a plastics manufacturing process. The manufacturing of plastics consists of two separate operations: (i) feedstock conversion and

(ii) compounding. First, feedstocks are converted into a number of core resins, which are stored in silos. Then, as customer orders are released for production, these resins are combined using an appropriate bill of materials and compounded to produce the final product. This end product is then packaged and shipped to the customer. Because products are offered in a wide variety of colors and grades, most customer orders end up being produced as separate lots.

The feedstock conversion operation is performed by resin plants that convert the primary raw materials of plastics, crude oil, and natural gas, into a number of different resins. Each resin has its own unique characteristics such as hardness, heat-resistance, and corrosion. The resins are stored in silos prior to their conversion to finished products by the compounding operation.

The compounding operation, which is the focus of this study, is ordinarily performed by 13 extruders, which extrude the finished product as pellets. After extrusion, the product is placed in containers called *v-bins* where quality tests are conducted on samples (Fig. 1). If samples are satisfactory, the finished product is moved into another type of container called a *hopper*, where it waits to be packaged. An extrusion line generally has two or three *v-bins* and one or two hoppers. Once in a hopper, the product must be packaged in either 55-lb bags or 1100-lb boxes, depending on customer order requirement. The division utilizes two bag-packaging stations and two box-packaging stations. Thus, the 13 extruders with a total of 22 hoppers must be packaged using these four packaging stations (Fig. 2). The existing configuration has six lines assigned to one pair of packaging stations (Bag 1 and Box 1), while the remaining seven lines utilize the other pair of packaging stations (Bag 2 and Box 2). A packager must be in attendance at each station during the packaging operation to help with sealing bags or boxes. At the time of the study, one packager attended to both Bag 1 and Box 1, while Bag 2 and Box 2 had dedicated packagers assigned to them.

As stated earlier, the packaging operations were unable to keep pace with the output from extruders. Consequently, as

Figure 1. After extrusion, the material goes to v-bins for quality tests before being placed in hoppers where they await packaging on a bag- or box-packaging station depending on customer requirement. Each extruder has 1 to 3 v-bins and 1 or 2 hoppers.

Figure 2. The 13 extruding lines are served by two pack systems, consisting of a bag- and a box-packaging station each. Six of the extruders connect to Pack system I, while the remaining seven connect to Pack system II. For clarity, the v-bins and hoppers between each extruder and the packaging system are not displayed.

material in hoppers and v-bins awaited packaging, the extruders had to be frequently stopped to prevent overflowing of these containers or mixing of different materials in the same containers. As a general

rule, if an extruder is blocked for more than one hour, it must be completely purged; that is, its contents must be discarded to avoid contamination. When extrusion lines are blocked, subsequent lots on the extruders

cannot be processed as scheduled, resulting in delays in fulfilling customer orders. In effect, they severely curtail the throughput of the plant. To alleviate these problems, the business had to outsource some of the packaging operations; the material was transported to a vendor, who packaged them in bags or boxes as necessary at a total cost of over \$250,000 per year. Management felt that the packaging bottleneck was due to insufficient packaging capacity. They created teams which identified four alternative packaging configurations that they believed would alleviate the packaging bottleneck. "Alternative 1" envisioned a separate pack system for lines L12 and L13 (Fig. 2); "Alternative 2" required a separate bagging system for lines L5 and L6 with L12 and L13 rerouted to Pack 1; "Alternative 3" would utilize connector lines such that lines utilizing Pack 1 could be routed to Pack 2 if the former was in use and the latter was available, and vice versa; and "Alternative 4" was to replace the two existing pack systems with a single new high speed high capacity bag pack for all lines. The management then requested the team to analyze the system to recommend the best alternative to implement. The team used a simulation model to analyze the packaging operations, as described in the next section.

CAPACITY ANALYSIS

To determine whether capacity was a cause of the problem of packaging operations' inability to keep up with production, the adequacy of the existing packaging capacity, and production scheduling practices were evaluated. Below, the authors discuss the manufacturing environment, production scheduling, and explain their discoveries.

The manufacturing environment in the plastics industry is characterized by multiple production (or extrusion) lines that are collocated in the same physical plant. While some of these lines may be dedicated to producing a single product, others can produce multiple products. The production schedules are determined considering the product demand, setup costs, inventory costs, and shortage cost.

Many papers have been published dealing with production scheduling in this manufacturing environment. In the case of a single production line, various aspects of scheduling have been investigated by Hsu [1], Gallego and Shaw [2], Jones and Inman [3], Gallego *et al.* [4], Dobson [5], Zipkin [6], Anderson [7], and Gallego and Moon [8]. Multiple production lines have been studied by Maxwell and Singh [9], Carreno [10], and Bollapragada and Rao [11]. Much of the literature deals with developing cyclical schedules under relatively constant product demands.

The company in which the packaging system that was simulated, developed, and eventually implemented has used a multistep proprietary system that includes the following steps. First, the corporate office looks at the book of business and determines which production orders must be fulfilled in the upcoming week. This is done while taking into consideration the aggregate production capacity and order delivery dates. The released orders are then forwarded to the manufacturing, which aggregates them into lots and develops production orders. It then assigns the production orders to individual extruders based on extruders' production capacities and the products that they can manufacture. Thus, at any point in time, the manufacturing facility has a rolling seven-day production schedule for the extruders.

Neither the literature nor the company's own legacy scheduling system, however, had addressed packaging operations. Plants generally manage packaging operations two ways. When production is stable with few cleanups between lots, sufficient packaging capacity capable of coping with the production can usually be installed. On the other hand, plants with unstable schedules often have to outsource part of the packaging operations to keep the extrusion lines operating. The latter case characterized the present operations as well. The division's book of business had become highly customized to the extent that production was characterized by large number of small lot sizes, requiring frequent cleanups of packaging containers and stations.

To effectively simulate the packaging system and evaluate its capacity, the team

started by base lining the existing system. Base lining refers to creating benchmark performance measures for the current system against which alternatives can be evaluated. This was done by developing a discrete-event simulation model of the existing plant configuration using ProModel simulation software. The model captured the material production and flows through extruders, v-bins, hoppers, and packaging stations as discussed earlier (Figs 1 and 2). Whenever a v-bin, hopper, or a packaging station processed a different lot, we added cleanup times requiring 15 min of packager's time to wash the station followed by 30 min of unattended drying. Other model features were v-bin and hopper capacities, extrusion rates, packager shifts, packager breaks and safety meetings, and packaging station breakdowns. We conducted time studies to determine packaging times to pack a bag or a box. When a packaging facility finished processing a lot, the next hopper was selected for processing by following the rule in force at that time: identify all hoppers that are at least half full, and then select the one that contains the lot with the earliest due date.

From historical data, a production week that had a normal production schedule was selected. All extrusion schedules were entered for that week into the simulation model to develop the baseline performance metrics. The team then successively modified the baseline model to implement each of the four alternative configurations and recorded the resulting performance metrics. The entire process was repeated with a light weekly schedule and a heavy weekly schedule.

Thus, the performance of the current system in each of the four alternatives was simulated under similar demand conditions. All configurations were evaluated on packaging cycle times, packaging stations utilization, packager utilization, average lateness, and number of line blockings. Analysis revealed that none of the alternatives fared significantly better than the existing system. But it was surprising to discover that the baseline system should be causing any bottlenecks

to begin with since the utilization of packagers and packaging stations was less than 30 percent.

The team concluded that the existing packaging capacity was more than sufficient to handle the output from extruders. Management was at first surprised by the team's conclusions, but eventually accepted our findings once we explained the actual simulation runs. It was obvious that actual packaging operations were not running as effectively as could have been expected. Further investigation as to why the packagers were unable to follow the prescribed rules revealed that the team found it very difficult to select the right hopper to package from, at the right time, from the more than 40 hoppers that are in the manufacturing facility. Consequently, packagers made up their own rules and would often process only the box stations, which were less physically demanding than the bag stations. The hoppers with material waiting to be bagged were being left unattended, leading to line blocking. Therefore, when presenting our analysis to the managers, the team proposed that a scheduling system be developed to generate efficient packaging schedules that could be easily followed by the packagers. The scheduling system would create this schedule so as to minimize the blocking of extruders. A formal statement of the packaging system formulation is presented next.

THE PACKAGING PROBLEM STATEMENT

The packaging problem that was used for the simulation of the packaging system can be stated formally as follows

Minimize Total number of extruder blockages

Subject to constraints on:

- lot processing times.
- lot sequencing.
- packager to facility assignments.
- setup times.
- V-bins and hopper contents and connectivity.

The objective is to minimize the total number of times that extruders are blocked over the time horizon for which schedules are generated. There are five sets of constraints: (i) lot-processing constraints incorporate scheduled start times and extrusion times once lot processing begins; (ii) lot-sequencing constraints should ensure that all bags or boxes of a lot on an extruder are completely packaged before packaging of the next lot on that extruder begins; (iii) packager-facility assignment constraints are necessary because Bag 1 and Box 1 share the same packager and thus, can never be used simultaneously; (iv) setup times constraints require packaging stations be cleaned after a lot change—this entails the packager washing the facility for 15 min and then letting the facility dry for 30 min. And finally, there are constraints that model the connectivity between each extruder's v-bins and hoppers and their contents. These constraints should make sure material flow from v-bins to hopper is restricted by the physical connectivity limitations and that a container never contains material from two different lots at the same time.

The team formulated the above problem as a mathematical model. This resulted in a large mixed-integer programming model that could not be solved in a reasonable amount of time using existing commercial math programming software. We therefore developed a heuristic scheduling algorithm, which is described in the next section.

THE PACKAGING SCHEDULING ALGORITHM

We use a discrete-time simulation-based heuristic scheduling algorithm to develop packaging schedules for a rolling horizon of one week. We divide the time horizon of one week into consecutive time periods of 15-min durations. The state of the system is maintained by each time period for the entire time horizon. The state of the system in a given time period include the current contents of the hoppers and v-bins, the jobs being processed by the extruders and the packaging stations, and the availability of the packagers. Our algorithm schedules

the packaging stations for the entire week, one period at a time starting from the first period. The underlying philosophy behind the algorithm is to package the output of the extruder that will be blocked at the earliest if no packaging stations were available. Then as some of the material is packaged from the extruder, the v-bins and hoppers start to empty out because the packaging rate is much higher than the extrusion rate. Even before the lot is completely packaged, the hoppers may be sufficiently empty so that this extruder will no longer be the earliest to be blocked. At this time, the extruder that now has the earliest blocking time is used. To avoid incurring frequent set-ups on the packaging equipment, it is ensured that a facility packages for a minimum amount of time before it switches to a new lot that requires a set up. This philosophy is implemented as explained below.

At the start of each time period, the blockage time of each extruder is computed. Blockage time is defined as the time before the extruder is blocked under the assumption that none of the materials in its v-bins and hoppers is packaged, and that the line continues to extrude its scheduled lots. The blockage time is computed using the jobs scheduled on the extruder, the production rate of the extruder, and the total available capacity in the v-bins and hoppers for storing the extruded material. The available storage capacity does not include unfilled storage space in a hopper or v-bin if it contains a different lot because different grades of plastics cannot be mixed. This situation may occur because it is possible for multiple lots to be awaiting packaging at an extruder. For example, the extruder may extrude a complete lot and place it in one hopper if the hopper is sufficiently large, and then proceed to place another extruded lot in the second hopper. Even the v-bins can be used for storage to prevent line blocking.

After computing the blockage times of all extruders, the extruders are sorted in the increasing order of blockage time. Starting from the first extruder in the sorted list, we attempt to schedule packaging for each extruder in the sorted list. To schedule packaging for a given extruder, we determine if

both the packaging facility needed to service that extruder and the packager assigned to that facility are available. If so, packaging for that extruder is scheduled. If this is a different lot for the packaging facility, a 45-min cleanup on the facility is scheduled. The next extruder in the list sorted by blockage times is then processed similarly. After all extruders have been processed for this time period, the state of the system for the rest

of the time horizon is updated. The updating included the quantities in the v-bins and hoppers based on the material that would be extruded and packaged during that time period, and the availability of the stations and packagers in the future time periods. The process for the next time period is then repeated, and continued until the end of the planning horizon. Our packaging algorithm can be summarized as follows.

Procedure Packaging_Algorithm

```

For period  $t = 1$  To NUM_PERIODS
    Compute extruder blockage times
    Sort extruders in the increasing order of blockage time
    For each extruder in the sorted list (starting from the top of the list)
        Check if the packaging facility needed by the extruder and the packager who
        operates that facility are available.
        If so, schedule packaging on the extruder for one time period. If this is a
        different lot for the packaging facility, schedule cleanup on that facility
        lasting 3 periods (45 min)
    Loop (next extruder)
    Update the system state for the rest of the time horizon.
Loop (next period  $t$ )
End procedure

```

SYSTEM IMPLEMENTATION AND USE

We implemented the scheduling algorithm in a web-based system, which we designed using Microsoft technologies: ASP, Visual Basic, VBScript, and MS-Access. The scheduling algorithm was coded in Visual Basic. The packaging schedules generated by the algorithm are saved in the packaging database that is implemented in Microsoft Access. A web interface using Visual Interdev was designed to extract the packaging schedules from the database and present to the user in a HTML format. The web server and the database reside on a Windows NT server. We provided a rich user interface with several options to view the schedules by date, shift, packaging facility, and packager. The packaging system interfaces with the smart tags database to retrieve information on current contents of v-bins and hoppers. These smart tags were installed to support the packaging system. We retrieved information on lots scheduled for production on each extruder line from the database supporting the master scheduling

system. Figure 3 shows the architecture of the system.

Shortly before the start of each shift, the shift leader ensures that the data in the system is accurate. The shift leader updates the database if any packaging facility is unavailable due to scheduled maintenance or breakdown, or if a packager is not available for any reason. He or she then issues the command to generate the packaging schedule for the next one week. The system now obtains real-time data on the current lot quantity in each v-bin and hopper, quantities that have already been packaged in bags and boxes, and the status of each packaging facility and packager. The extruder schedules are then obtained from the extruder schedules database.

The system then executes the scheduling algorithm and stores the results in the packaging database. The two most important outputs of the algorithm are packaging schedules for each packaging station, and the packager schedules for each packager. The packaging schedule (Fig. 4) shows the different extrusion lines and lots the facility would be packaging. Cleanup operations between

Figure 3. The packaging system resides on a Microsoft ASP server. It retrieves information on current contents of v-bins and hoppers from the smart tag application database and the extruder line schedules from the extruder schedules database. The scheduling engine written in Visual Basic generates schedules for packaging lines and packagers and saves them into the packaging database.

lot changes are also included. An important benefit of this report is that it shows times when the facility is idle so that maintenance operations can be performed if necessary. The packager schedules (Fig. 5) are created for each packager and show the packaging stations and corresponding lots the packager must attend to during the shift. Packagers' scheduled lunch and coffee breaks, and mandatory meetings are also built into the report. Idle times are also displayed which are used by packagers to plan nonpackaging related activities.

The packaging schedule is regenerated with fresh data at the beginning of each shift for a one-week rolling time horizon. Clearly, only the schedule for the shift is of interest to the packagers; however, the week-long schedule gives management visibility to upcoming load at the packaging stations. There are occasions when a new schedule needs to be developed in-between a shift if

some events cause the actual packaging operations to deviate from the proposed schedules. For example, a packaging facility may break down causing some of the extruders feeding into it to be blocked. Or, the business may rush through an important last minute order, which would also throw the actual operations out of kilter with the schedule. When these events occur, the personnel on the plant floor deal with the immediate situation as best as they can and then the shift lead regenerates the schedule from that time onwards.

BENEFITS AND SUMMARY

After an initial two-month phase-in period, during which packaging schedules were thoroughly reviewed for completeness and efficiency, and system bugs identified and fixed, the packaging system was placed into production in January, 2004, just as the demand for

The screenshot displays the 'Bagging Schedule' window. Figure 5. For each packager, a schedule is generated showing which stations the packager should be attending during the shift. It also displays the times when the packager is on a break or busy in mandatory meetings.

the division's products began to pick up with improving economy. The project resulted in the following benefits:

- *Reduced Capital Investment Costs.* The simulation analysis clearly showed that existing packaging capacity and the number of packagers utilized were sufficient for a capacity of up to 3.5 million lbs per week. This prevented an unnecessary capacity expansion project that would have required over a million dollars in capital expenditure.
- *Increased Capacity.* After the system had been in use for a while, often with increased loads, the management concluded that by removing packaging as bottleneck, the throughput capacity of the plant has been effectively increased by 20%, or about 30 million lbs per year.
- *Increased Efficiencies.* Packagers now get their schedule at the beginning of each shift showing where they need to be at what time for the duration of the shift. Since the packagers have visibility to their schedules, they can better utilize their "idle time" for other tasks.
- *Personnel Savings.* The manufacturing operations are performed 24 hours a day, 7 days a week, in three daily shifts. To accommodate a five-day workweek, four teams of packagers rotate through the shifts during a week. Improved scheduling resulted in one full time equivalent (FTE) worth of personnel idle time per shift. Packagers now use this idle time to load the material into trailers themselves, a task previously done by the warehouse personnel. This has allowed for a total reduction of four FTEs from the warehouse staff of 16 personnel that formed the four shift teams, or 25% of the personnel cost.
- *Outsourcing Costs.* Outsourcing of packaging was reduced by 50% (some orders still require specialized packaging), saving another \$125,000 per year.
- *Maintenance Planning.* The system generates a rolling seven-day schedule at the beginning of each shift. This gives sufficient advance visibility to idle times

at packaging stations so that plant personnel can perform maintenance operations without affecting plant throughput.

In this article, we have described a scheduling problem encountered in the plastics industry. The bottleneck in the packaging operations was affecting the efficiency of the extruding operations. After an initial simulation-based capacity analysis that showed that packaging stations had sufficient capacity, we turned our attention to improving scheduling at those stations. We developed and implemented a packaging scheduling system that creates a schedule for each packaging station and for each packager. By removing the packaging operations as a bottleneck, the system effectively increased the throughput capacity of the manufacturing operations and also eliminated the need for outsourcing of packaging operations. The main lesson we learnt was that when dealing with complex manufacturing systems, the obvious solution might not be the correct solution. In this project, the obvious solution of increasing the packaging capacity would not have achieved the desired results, as we learnt from the capacity analysis that was performed via simulation. This project clearly illustrated the need to involve operations research experts in analyzing complex manufacturing systems.

IMPROVING PUBLIC HEALTH IN DEVELOPING COUNTRIES THROUGH OPERATIONS RESEARCH

PRASHANT YADAV
MIT-Zaragoza International
Logistics Program, Zaragoza
Logistics Center, Zaragoza,
Spain

Public health involves improving the health of a community (as opposed to an individual) by preventive measures, control and treatment of communicable diseases, health education, regular monitoring, and surveillance of diseases. Activities in ensuring public health can be generally classified as “public goods.” The benefits from public health activities are of a community nature and its mode of delivery does not always allow targeting and exclusion. It typically costs very little for an additional individual to enjoy the benefits accruing from a public health intervention and it is generally difficult or impossible to exclude individuals from consuming the benefits. A fundamental problem with public health (and more generally all public goods) is the inability of all segments of the population to pay for health and in some cases, the difficulty of motivating individuals to pay because a portion of the resulting benefits from public health expenditures are benefit externalities for them. Poverty and more competing needs for expenditure severely limit the ability of large segments of the population in the developing world to pay for better health. Public health is therefore mostly financed by national governments with the objective of controlling the spread of disease and ensuring better health of their citizens or by supranational agencies to ensure better global health. The resources committed to public health are generated from tax and other governmental revenues and thus lend themselves as ideal candidates for using operations research (OR) techniques in resource allocation and deployment. In the last century, we have seen remarkable progress in

the field of public health in large parts of the world, a part of which can be attributed to the use of scientific methods to allocate and deploy public health interventions.

Unfortunately, the spread of infectious diseases such as HIV/AIDS and the resurgence of malaria combined with severe resource constraints have resulted in little progress on this front in low income countries, especially in sub-Saharan Africa. As an example, the average life expectancy is merely 39.6 years in Swaziland and 42.1 years in Zambia as compared to 82.6 years in Japan or 78.2 years in the United States (the world average is 67 years) [1]. The public health situation in low income countries today corresponds in many respects to the situation observed in the rich OECD countries a few decades ago. However, the technical and scientific knowledge for overcoming some of the diseases such as diphtheria, diarrhea, typhoid fever, and malaria already exists now. In addition, reasonable (although not sufficient) financial resources have been committed by institutions such as the Global Fund to Fight AIDS, TB, and Malaria and the US President’s Emergency Program for AIDS Relief to counter these diseases. Unlike in the OECD countries where health care is financed either through government or individual private expenditure, financial resources for improvement of health in developing countries come from a variety of sources including bilateral government aid, multilateral aid institutions, private philanthropic organizations, other non-governmental organizations (NGOs), and government loan readjustments with the World Bank (Fig. 1).

This variety in the sources of financing further exacerbates the complexities in resource allocation because not-for-profit, government, and for-profit stakeholders very often have different objectives. Given the overall scarcity of resources and a complex multistakeholder environment, the foremost need in developing countries is now to apply OR techniques to ensure the optimal

Figure 1. Sources of financing for global health. [Source: Source data obtained from the Institute for Health Metrics and Evaluation. <http://www.healthmetricsandevaluation.org/resources/datasets/2009/dah.html>]

allocation, utilization, and deployment of the available economic and material resources. OR can be applied to optimize efficiency of different public health programs in countries with high disease burdens and scarce resources. As an illustration, the budget allocated to OR in grants allocated by the Global Fund increased from a total of US \$42 million for all grants between 2001 and 2005 to US \$27.3 million for grants in 2006 alone [2].

OR techniques have traditionally been used in the field of health care for a range of problems such as hospital capacity planning, health-care facility location, outcomes and pharmaco-economic analysis [3]. This article will provide an introductory overview for an OR practitioner/researcher considering applications of OR which have specific relevance to public health in the developing world. The purpose is not to provide a comprehensive survey nor a taxonomy of OR problems in public health in developing countries but instead to provide the reader an overview of the nature of problems in global public health that are suitable for the use of OR techniques.

OPERATIONS RESEARCH IN PUBLIC HEALTH: DEFINITIONAL ISSUES

A review of literature and technical reports in public health reveals that the definition of public health and even more so the definition of OR varies significantly amongst public health practitioners and researchers. A quick review of the existing definitions is presented before we delve further into the topic.

Winslow [4] first defined public health as “the science and art of preventing disease, prolonging life, and promoting health through the organized efforts and informed choices of society, organizations, public and private, communities and individuals.” In a more recent definition, the Institute of Medicine [5] defines public health as “fulfilling society’s interest in assuring conditions in which people can be healthy by applying scientific and technical knowledge to prevent disease and promote health.” For a more detailed discussion on activities that are considered as public health, see Ref. 6.

Similarly, a review of the OR activity description of the Global Fund, the WHO

and various other agencies involved in public health revealed that a commonly accepted definition is “the use of systematic research techniques to provide policy makers and program managers with evidence that they can use to improve program performance.” The definition in public health practice is in tune with the early definition by Morse and Kimball [7] and Waddington [8], which includes activities such as impact assessment, outcome measurement, and metric design as a key part of OR. In this article, we work with a more restrictive definition, that is, “the use of mathematical models, statistics and algorithms to aid in decision making with the goal of optimizing performance on specific metrics.”

KEY METRICS IN PUBLIC HEALTH

Although the core techniques of OR do not change much upon their application in public health, the nature of the objective function and output metrics are considerably different in many cases. As public health deals with the overall state of health of the population, almost all analysis hinges on being able to measure the state of health. Public health operational research also focuses on the efficiency of an intervention through the use of cost-effective measures. The costs and public health effects of an intervention are assessed to determine whether the public health intervention is worthwhile from an economic perspective. When resources are inadequate to meet all possible health needs—as they almost always are in the case of developing countries—being able to quantify the outcomes using a common health metric aids the efficiency of resource allocation. Several different measures have thus been proposed and we present the most commonly used ones. Some of these metrics are also widely used in health care OR.

Mortality

Mortality rate is a key measure of the health of a population and captures the number of individuals who die each year by age, sex, and the cause of death classified according to standard medical criterion. Most countries

collect such data but the quality, coverage, and completeness varies significantly. A 2003 WHO study [9] found that there are 28 countries where less than 70% of the mortality data are complete or an incorrect cause of death was assigned to more than 20% of deaths.

Morbidity

The number of cases of a particular disease occurring in a year is usually reported as cases per 1000. When looking at morbidity it is important to differentiate between *prevalence* and *incidence*.

Incidence describes the occurrence of new disease in the population in a given time period, whereas *prevalence* is a static measure of the proportion of a population that has the given disease, whether the disease cases occurred recently or at some previous point in time. For infectious diseases of short duration such as malaria or diarrhea, the differences are not significant between the two, but for more chronic communicable diseases such as HIV/AIDS and sexually transmitted infections, there are significant differences between prevalence and incidence.

Life Expectancy

Life expectancy measures the average remaining life span of individuals in a given population group. A commonly used measure is life expectancy at birth.

The above metrics only measure the impact of disease or ill-health as either death or prevalence/incidence. The longer term impacts of disease such as disability and loss of quality of life have a significant cost to the society and an overall public health impact but they are not considered in the three metrics presented earlier. Quality-adjusted life year (QALY) and Disability-adjusted life year (DALY) are two economic measures of health that combine the duration and quality of life.

Quality-Adjusted Life Year (QALY)

QALY is a metric which measures the duration and quality of life [10]. The number of QALYs lived by an individual in one year

is equal to the health-related quality of life weight attached to that year of the individual's life. An individual's quality-adjusted life expectancy at age a can be written as $\sum_{t=a}^{a+L} Q_t$ where L is the remaining life expectancy at a . However, the value of life in a given year is not the same as life in future years and hence a discount factor δ is used. Typically a 3% discount factor is used [11].

Thus, QALYs gained as a result of a specific intervention can be written as $\sum_{t=a}^{a+L^i} \frac{Q_t^i}{(1+\delta)^t} - \sum_{t=a}^{a+L} \frac{Q_t}{(1+\delta)^t}$, where Q_t^i and Q_t represent the quality of life weight with and without the intervention respectively for each time period t and L^i is the remaining life expectancy after the intervention. It is important to note that QALYs do not have an age-weighting function, that is, apart from discounting one QALY has the same value regardless of the age at which it is lived.

Disability-Adjusted Life Year (DALY)

A DALY is a health outcome measure which like the QALY measures both the quality of life reduced due to a disability after the disease and the lifetime lost due to premature mortality. One DALY can be viewed as one lost year of "healthy" life. The concept of DALY was first presented in World Bank [12]. $DALY = YLL + YLD$, where YLL are the years of life lost due to premature mortality (average life expectancy at age of death due to disease) and YLD are the years lost due to disability. YLD are calculated by multiplying the number of cases of the disease by the average duration of a case and a specifically chosen disability weight for each health condition. The disability weight is determined by expert valuations on a scale from 0 (perfect health) to 1 (death).

A key difference between the DALY and the QALY is that in DALY calculations the value attached to life is weighted so that years of life in childhood and old age are counted less [13]. Also, DALY involves continuous discounting, whereas QALY is based on discrete discounting. Ignoring continuous discounting, age weighting and the way the disability/quality scores are computed, one DALY saved compares to one QALY gained, that is, $QALY = 1 - DALY$.

There has been considerable critique of the DALY (and QALY) as a metric for resource allocation decisions in public health [13,14]. One of the main critiques is its use of different age weights in order to capture lesser economic value creation as a child or as an older person. However, such weighting may work against resource allocations that alleviate diseases prevalent only in children in favor of those diseases that are more prevalent in working adults. Additionally, public health interventions often result in nonhealth related economic benefits and using DALY minimization as the objective in resource allocation may ignore some of these interrelationships [14]. Also, when used for resource allocation, DALY discriminates against those who are already disabled as their DALYs are lower.

Public health OR modelers require metrics so that health outcomes can be expressed in common units to analyze the trade-offs between health and economic benefits. Measuring health outcomes in common units is such a complex process that some of these shortcomings are likely to be present in any economic metric created for this purpose. Despite the shortcomings, QALY and DALY continue to be used as a metric for measuring the impact of health interventions. While QALYs are more commonly used in developed countries, DALYs are used for measuring burden of disease and cost-effectiveness of health interventions in low income countries. Threshold values on cost per DALY saved with a public health intervention in developing countries have emerged as thumb-rules for practitioners in the field of public health to accept or reject an intervention. A common threshold for interventions in low income countries is \$100 per DALY saved [15].

Table 1 shows some common interventions in developing countries and their cost-effectiveness ratios measured in US\$/DALY averted. The ranges of the cost-effectiveness ratios for many of these interventions are wide and vary according to the local setting due to varying ability to target specific populations. It is also evident that although the \$100 per DALY averted thumb rule is mostly used, in instances such as HIV/AIDS where the disease can have a much wider

Table 1. Cost-effectiveness (US\$/DALY) for Some Common Public Health Interventions in Developing Countries

Disease	Intervention	Cost Effectiveness (US\$/DALY)	Cost Effectiveness Range (US\$/DALY)
HIV/AIDS	Antiretroviral therapy	922	350–1494
HIV/AIDS	Condom promotion and distribution	82	52–112
HIV/AIDS	Mother-to-child transmission prevention	192	7–377
HIV/AIDS	Peer and education programs for high-risk groups	37	6–68
HIV/AIDS	Treatment of opportunistic infections	156	3–310
HIV/AIDS	Voluntary counseling and testing	47	10–85
Malaria	Insecticide treated bed-nets	11	5–17
Malaria	Intermittent preventive treatment in pregnancy with sulfadoxinepyrimethamine	19	13–24
Malaria	Residual household spraying	17	9–24
Tuberculosis	Directly observed short-course chemotherapy	301	84–551
Traffic accidents	Increased speeding penalties, enforcement, media campaigns, and speed bumps	21	3–38

[Source: Data obtained from disease control priorities project. <http://www.dcp2.org>.]

social impact than captured in DALYs, resources are allocated to recommended interventions such antiretro viral treatment despite their high cost per DALY averted.

DISTRIBUTIONAL EQUITY CONSIDERATIONS IN PUBLIC HEALTH

OR models for public health are distinct from other OR models because apart from commonly used objectives such as profit, output, and costs, they often also consider *equity of outcomes*. Effective public health requires that there are no large disparities between the availability of medicines, preventive health services, and other inputs across different socioeconomic segments of the population. OR models commonly incorporate equity constructs by setting constraints on minimum and/or maximum levels of an output provided to a given socioeconomic segment and in some cases by minimizing the sum of absolute deviations from the mean level of product or service provision.

A commonly used measure is the concentration curve, which is a plot of the cumulative proportion of the specific health-related variable being measured (income, health, medicine availability, distance to nearest facility etc.) against the cumulative

proportion of the population ranked by income, beginning with the poorest, and ending with the richest. Equality on the curve is represented by a diagonal line of slope 1, and the greater the deviation of the curve from this line, the greater the inequality. So for instance, if everyone, irrespective of his or her income, has exactly the same value of the variable which measures poor health status, the concentration curve will be a 45-degree line. On the other hand, if the health variable takes higher values (reflecting poorer health status) among poorer people, the concentration curve will lie above the line of equality. The farther the curve is above the line of equality, the more concentrated is poor health among the poor.

Figure 2 shows the infant mortality measured as deaths of children under five years of age against the cumulative births ranked by income. The curve for India lies above the line of equality, indicating that under-five child deaths in India are concentrated among the poor. In comparison, the Mali curve lies everywhere below that of India implying there is less inequality in under-five child deaths in Mali than in India.

Such concentration curves provide useful visual representation of inequality but provide limited ability to rigorously compare the

Figure 2. Lorenz curves for under-five deaths in India and Mali. *Source:* Doorslae. *et al.* 2008 [16].

Table 2. Gini Index of Health Facilities in the Lagos State of Nigeria

Facility Type	Gini Index
Primary health center	0.12107
Public secondary health facility	0.32567
Private hospital	0.23163
Public and private secondary health facilities	0.14015

[Source: Data obtained from Oguntade and N.A. Yusuph [18].]

extent of inequality across units of geographical analysis and over time. Different curves can be superimposed on each other as in Fig. 2 to see the difference but the number of such comparisons is limited.

An alternative method is thus to compute the Gini coefficient [17] of the public health input or output metric. The Gini coefficient G is defined as the mean of absolute differences between all pairs of individuals for a chosen measure.

$$G = \frac{\sum_{i=1}^n \sum_{j=1}^n |x_i - x_j|}{2n^2 \bar{x}},$$

where x_i = observed value of the measure, $\bar{x}$ = mean of the observations, and n = number of observations. The minimum value of G is 0 implying perfect distributional equality and the maximum value is 1 which is perfect inequality (implying one individual possesses all of that measure).

A very common use of the Gini coefficient is to measure the distribution of access to health facilities by population in facility location problems or the distribution of availability of drugs by socioeconomic quintiles. Table 2 shows the Gini coefficient for the state of Lagos in Nigeria for different types of health facilities. If the entire population has perfectly equal access to a health facility, the Gini coefficients would be 0.

The success of vaccination programs in low income countries typically is measured not just on the total number or proportion of children vaccinated but the Gini coefficient is calculated to understand any distributional inequities. Design of targeted programs for vaccination, the location of new vaccination clinics and mass distribution campaigns are all driven by such analysis.

BASICS OF DISEASE MODELING

Understanding and quantifying the impact of public health interventions requires some preliminary understanding of disease transmission. Although a detailed discussion of disease transmission model is beyond the scope of this article, a basic model of disease transmission is discussed to give the OR practitioner a general idea. Ross [19] first developed a mathematical model of infectious disease transmission, which was used extensively by Macdonald [20] for studying malaria transmission. Commonly known as the Ross and McDonald model, it is now the basic building block in our understanding of disease transmission.

Most disease models are compartmental models and in the simplest sense they split the human population into a proportion of those who are susceptible to an infection, those who are infected, and those who have recovered and acquired temporary or permanent immunity (Fig. 3). Recovered and immune individuals can return back to the susceptible state after a certain period and birth and natural or disease induced death occur in the different compartments. The changes in the proportions of these three categories are described by differential equations where the parameters are estimated from field studies and vary depending upon the nature of the disease and infection dynamics. Models with more number of

states (or compartments) are closer at depicting reality but the resulting system of differential equations becomes complex to solve. For a detailed discussion of dynamic models of disease progression, see Anderson and May [21].

A key parameter of the disease model is the basic reproduction rate R_0 , which is the number of secondary infections that can arise when a single infected individual is introduced into a population where everyone is susceptible. Very simply stated, if $R_0 = 2$, there will be two new individuals who will be infected in the first round of transmission, 4 in the second, 8 in the third, and so on. If $R_0 = 100$, there will be 100 secondary infections in the first round, 10,000 in the second, and so on. In reality, the dynamics are more complicated as the susceptible population itself changes. Theoretically, if $R_0 > 1$, the number of infected people will grow exponentially until the entire population is infected. In reality, however, the development of immunity and other factors may arrest the development of disease. If $R_0 < 1$, the number of cases declines exponentially until the infectious disease can be eliminated or eradicated. Using malaria as an example we present some more details of the Ross and McDonald model

$$R_0 = \frac{ma^2 p^n l}{-\log_e p},$$

Figure 3. Basic compartmental model of malaria transmission.

where m is the number of female mosquitoes per person in the region, a is the rate at which each mosquito bites, p is the proportion of mosquitoes that survive from one day to the next, n is the maturation period of the parasite in the mosquito, and l is the duration of a single infection.

The rate a at which mosquitoes bite appears as a squared term because a cycle of transmission requires one bite to infect the mosquito and one to pass the infection back to a human. More involved versions of the model also include a probability that a bite from an infected mosquito results in human infection.

The interventions to control malaria can be broadly categorized into three main types: indoor residual spraying, distributing insecticide treated bed-nets, and treatment or prophylaxis with drugs. Transmission of malaria is influenced by many factors and an operations researcher needs to understand which interventions will have the strongest impact on reducing transmission in order to be able to develop allocation models. The above model makes it clear that measures which can reduce p , the proportion of (infected) mosquitoes that survive, is far more beneficial in reducing disease transmission than, for example, insecticidal spraying on mosquito breeding sites, which only impacts m . We can also see that parasite elimination through prompt treatment of infected individuals is also very beneficial as it decreases the duration of an infection l but may also indirectly decrease a . This demonstrates why a good understanding of the underlying disease transmission model is essential for building usable OR models for public health.

Admittedly, the above model was a simplified model only to illustrate how understanding and modeling of disease models remain key for optimal resource allocation. In reality, however, most infection transmission models have nonlinearities that can either lead to stable or unstable equilibrium points. Analysis of resource allocation decisions where disease progression follows a nonlinear transmission presents a complex problem which requires sophisticated OR techniques to solve.

OPERATIONS RESEARCH AND RESOURCE ALLOCATION FOR PUBLIC HEALTH INTERVENTIONS

Public health policy makers at different levels (global, national regional) face a range of resource allocation problems. First, they have to decide the allocation of resources between different diseases (e.g., malaria, HIV/AIDS, diarrhea, tuberculosis, maternal health); secondly, the allocation of resource between multiple interventions within each disease area (e.g., indoor insecticide spraying, distribution of bed-nets, distribution of medicines for treatment, and chemoprophylaxis); and thirdly, the allocation of resources to specific operational and tactical models for delivery of each intervention. As discussed in the section titled “Key Metrics in Public Health,” a commonly used method for resource allocation is cost-effectiveness analysis based on cost per DALYs saved or cost per QALY gained. Notwithstanding the shortcomings of QALYs and DALYs, other issues further exacerbate the complexity of public health resource allocation decisions. Some of these include nonconstant returns to scale; differences in measures of cost-effectiveness; high dependence of cost-effectiveness on the spatial distribution of incidence; trade-off between increased efficiency and effectiveness through intervention targeting versus ensuring distributional equity; and interconnectedness of returns from each intervention. We start with a simple example to illustrate resource allocation in public health.

Imagine there are two diseases: Disease A kills 5000 people per year, and Disease B kills only 50 people per year. It costs \$100 per person to prevent people from dying of Disease A and \$50 per person to prevent death from Disease B. The public health resource allocator has \$10,000 for disease control. How should he spend the money? Note that a naïve public resource allocator would set priorities based on the high mortality from Disease A and allocate all the resources available (\$10,000) to Disease A and save 100 lives. If the objective is to maximize the total number of lives saved, a simple linear programming formulation would give us the optimal resource

allocation.

x_A = Budget allocated to Disease A,

x_B = Budget allocated to Disease B

Maximize number of lives saved = $\frac{x_A}{100} + \frac{x_B}{50}$

Subject to

$$x_A + x_B = 10,000$$

$$\frac{x_A}{100} \leq 5,000; \frac{x_B}{50} \leq 50.$$

Clearly, the optimal allocation is $x_A = \$7500$ and $x_B = \$2500$ with a total of 125 lives saved.

Typically, the cost of interventions are not linear. For example, it is easier and cheaper to conduct insecticide spraying (or drug distribution) in urban areas as populations are easier to reach and population density is higher. The cost of spraying (or drug distribution) is much higher for rural populations, which are more difficult to reach [22]. Thus, the cost per-unit of output for an intervention depends upon the level of that intervention. A piecewise linear model with decreasing returns is commonly used to capture this in public health resource allocation models. Often, it is also difficult to separate the benefits from each intervention.

The cost per DALY saved in Table 3 is an average measure for each intervention and they vary considerably across and within countries depending on the degree of malaria

incidence [24]. The wide ranges in the cost per DALY saved is attributed to challenges in measurement due to varying scales of the intervention and nonlinearity in the costs. This shows that the design of optimal resource allocation models has to be region- and context-specific as they will depend on the level of disease incidence, current scale of existing interventions, geo-spatial distribution of populations at risk, and other health infrastructure related issues. Resource allocation managers and public health OR analysts must acknowledge that it is not going to be easy to obtain specific recent estimates of the cost-effectiveness of every intervention for each specific context. Therefore, OR models need to be built based on results from other contexts using carefully selected extrapolation and statistical matching methods.

One approach to enhance the allocative efficiency between different interventions is to stratify regions in terms of their epidemiology, sociology, and other characteristics and select targeted region-specific interventions. However, this approach may also lead to lower distributional equity of the interventions or their outcomes. Carefully managing the dual objectives of efficiency and equity is a challenge that resource allocation managers in public health constantly face. In addition to the distributional equity considerations, epidemiological or sociodemographic data is hard to obtain in low income countries, which often makes the costs of identifying and/or stratifying the target populations extremely high.

In the long term, resource allocation decisions are a vector of allocations to each intervention for each time period and the optimal allocation will vary considerably based on whether the objective is to eradicate a disease or control a disease. The dynamics of disease progressions imply that there is high degree of complementarity between the interventions and the presence of one intervention positively impacts the benefits from the other. Such interrelationships become complex to model in traditional OR models and sometimes require systems dynamic models [25]. Similarly, there are positive

Table 3. Cost-Effectiveness of Selected Malaria Interventions

Intervention	Cost per DALY Saved (Range)
Insecticide treated bed-nets (net + insecticide treatment)	\$11–\$17
Indoor residual spraying (1 round)	\$9–\$12
Indoor residual spraying (2 rounds)	\$17–\$24
Intermittent preventive therapy during pregnancy	\$13–\$24

[Source: Data obtained from Jamieson *et al.* [23], *Disease Control Priorities in Developing Countries*, 2nd edition, 2006.]

complementarities across disease-specific interventions implying that a disease-specific public health intervention has benefits for other diseases.

EXAMPLES OF OR PROBLEMS IN PUBLIC HEALTH

With a background on the metrics, objectives, and other notable considerations in OR for public health, we now turn to a few application areas. In Table 4, we present the most commonly observed challenges in developing country public health programs and the nature of OR models that could potentially be used to address that problem.

We describe a few important classes of problems which have particular relevance to public health in the developing world.

Facility Location Problems

Facility location problems have been a cornerstone of OR since the work of Weber [26], who considered the problem of locating a warehouse to minimize the total travel distance between the warehouse and a set of customers. Much later, Hakimi [27] considered the more general problem of locating one or more facilities to minimize either the sum of distances or the maximum distance between facilities and customers. Determining the optimal number of facilities was also considered in many location models. For a detailed review on facility location problems, see Brandeau and Chiu [28].

In traditional facility location models, the objective is to minimize either the weighted sum of distance or the maximum distance traveled. However, a public health planner may want to minimize the maximum distance (or a nonlinear function of maximum distance) traveled to capture the equity considerations presented earlier. The model of Maimon [29], which looks at facility location for public sector applications by incorporating equity and variance of distance traveled in the formulation is particularly applicable to public health settings. Similarly, the model of Schilling [30] considers multiple objectives in locating facilities with public sector objectives.

Traditional location models work under the assumption that individuals choose the facility that is closest to them. Given the social stigma associated with diseases such as HIV/AIDS and sexually transmitted infections, individuals in a public health setting may not always choose facilities closest to them. Literature in public health also shows that attendance at public health clinics falls with increasing distance to the facility [31,32]. For diseases such as TB and HIV/AIDS that require long-term treatment nonadherence to treatment can lead to higher costs as nonadhering patients migrate from first-line to more costly second-line treatment. For TB, Shargie and Lindtjörn [32] show that treatment adherence decreases as distance traveled by patients to the clinic increases. Using that premise [33] investigated the impact of patients' travel

Table 4. Public Health Challenges in Developing Countries and Potential OR Models

Public Health Challenge in Developing Countries	Potential OR Models
Poor physical accessibility to health facilities	• Facility location
High waiting time at public health facilities	• Capacity management
Acute shortage of health care workers	• Capacity management • Staff deployment
Nonavailability/shortages of drugs, vaccines, and other health products at public health facilities	• Network design • Optimal multiechelon inventory control • Inventory rationing

distance to HIV/AIDS clinics on treatment adherence and developed a model for locating new HIV/AIDS clinics in Zambia to maximize adhering population. Their simulation model shows that taking into account patient attendance and adherence in optimal ARV facility location placement could lead to a potential 3% increase in patients starting and adhering to treatment.

Another area of concern to public health is the average or maximum response time of a facility location model to contain disease outbreaks. In such circumstances, opening new temporary facilities to quickly distribute (vaccines, drugs, and therapeutics) to the affected population [34,35] is an effective outbreak containment strategy. The economic trade-off is between the number of facilities to open and the facility capacity versus the distance traveled and its impact on outbreak containment. OR models [35] determine *how many* new facilities should be opened and where and also rules on the assignment of individuals to the facilities. Heier *et al.* [36] consider the more general problem of decentralized facility assignment in such a scenario when the users pick the facility themselves and establish the cost of “anarchy” in such a system. They show that in some cases when patients pick their facilities based on full information about facility status and travel distances, it results in greater total travel time than a centralized solution where patients are allocated to facilities or when patients do not have full information about facility status.

Another key concern for public health in developing countries is the performance of a facility model when hospital infections such as MRSA (methicillin-resistant *Staphylococcus aureus*) or machine and equipment failures that are common in developing countries could temporarily shut down a health clinic. Berman *et al.* [37] look at the classical p -median facility location problem and introduce the possibility that a facility might suffer a disruption. Using the example of Toronto hospitals, they show that considering the probability of failure in the facility location model results in a higher degree of centralization. Their results corroborate the colocation and centralization

observed in Toronto and many other hospital systems.

The choice of the location of public health facilities is a key strategic decision variable in the design of public health systems. OR techniques with carefully selected objectives functions can help find facility locations which can maximize public health impact through better access to those requiring treatment or preventive interventions. Future research could focus on incorporating patient's health facility choice models and other benefit externalities into the optimal facility location problem.

Capacity Management Models

The emergence of new infectious diseases or the resurgence of old ones like malaria suddenly presented additional demand on the public health system, but the system could not develop as quickly due to financial and human resource constraints. The lack of human resource capacity is illustrated by the fact that sub-Saharan Africa which has over 25% of the global burden of disease has only 2–3% of the world's health workers. Unfortunately, the money to hire, train, and sustain new health care workers is not available and is not likely to be available in the medium term [38]. This acute scarcity of health care workers in developing countries, especially in sub-Saharan Africa, offers limited ability in the short- to medium-term to apply models that help determine optimal staffing or capacity levels for clinics. The proper deployment of health staff and careful management of the available capacity in clinics can be a key approach to maximizing public health outcome in such an environment. This is currently lacking and long queues continue to form at many points within the public health system.

Many different queueing models for capacity management in health-care setting have been developed [39,40]. An important point of difference in the case of public health clinics in developing countries is that in many cases average capacity to serve patients is less than the arrival capacity. Thus, in such systems, patients renegeing or service rationing is the only way that a system can attain the state of equilibrium;

otherwise, queue lengths keep increasing with time (the analysis of transient queue behavior is beyond the scope of this article). When server utilization is very high, average waiting time can be minimized by giving priority to patients who require shorter service times. Thus, the shortest processing time rule instead of the first-in first-out queue discipline could minimize total waiting times. However, such a rule is difficult to implement in practice due to its perceived unfairness amongst the patients especially in single server systems. If there were two servers, a system like the one observed commonly in supermarkets where there is dedicated express service counter for shorter processing time customers could be envisaged. Using a lesser trained health worker to treat shorter processing time patients can be an effective means of capacity management in public clinics. Thus, a triage step to know patient needs when they enter the queue is important whether to enforce the shortest processing time discipline or direct them to the lesser trained health worker. In reality, health systems are organized as tiered networks with referrals from one stage to the other. Thus, an overall analysis of public health systems requires analyzing queueing networks. Discrete event simulation could thus be a very important OR technique to utilize in the public health system. An overview of applications of discrete event simulation in health care can be found in Ref. 41. Also Hopp and Spearman [42] provide easy to use queueing approximations which can be used for modeling multistation public health systems and to analyze the impact of different parameters and flow arrangements in a public health clinic on waiting time, throughput, and variability propagation.

Since public health is usually free and does not involve any price mechanisms to regulate demand and supply, revenue management based methods of service differentiation or capacity management are not applicable in this setting. Pure rationing to restrict demand is not ethical and creates many sociocultural problems. The renege process works in a manner that individuals who can afford to obtain care at other locations quickly drop out of the system. The

long waiting time in public health clinics in some developing countries acts as a rationing system which favors those who have a low opportunity cost of time and penalizes those who have short or long term formal employment [43]. Thus, on the surface it appears that long queueing automatically leads to socially efficient rationing on the basis of socioeconomic factors. In reality, however, informal arrangements lead to queue jumping which benefits those with more resources making the queue renege phenomenon into an inequitable and unjust rationing approach. Queueing based analysis, nevertheless, can be an important tool to devise capacity management strategies for public health clinics in developing countries. Future research could focus on modeling the impact of different task shifting interventions (point-of-care testing, nurse triage, telemedicine, decoupling drug dispensing from care provision) and varying queue disciplines in developing country health programs with severe capacity constraints.

Stock Rationing Models

Availability of drugs, vaccines, and other health supplies is very low at the clinic levels in many developing countries. Average availability at public health facilities in certain regions within a group of 36 surveyed countries was as low as 29.4% [44]. The typical structure for distribution of medicines in the public sector in most developing countries consists of a central/primary warehousing and distribution point which supplies to one or two downstream stock holding points depending upon the distribution of population and administrative structure of a country. The level of availability is low at each of the stocking points in the supply chain and thus each stage in the system has to engage in stock rationing. In systems where stock rationing is very common, if the rationing is done based on a fixed proportion of the order size, each downstream unit (clinics or sub-warehouses) inflates its orders to get a bigger share of the available supply [45,46]. If past consumption is used to allocate stock [46], changes in seasonality

and consumption patterns as a result of epidemiological patterns or differential coverage of preventive interventions are not adequately captured. In addition, the degree of lost sales at each clinic continues to get repeated in the future.

The traditional models of inventory rationing in OR analyze the problem of how to allocate inventory to different customer classes [47,48] by setting a threshold of inventory for each class of customers. Most of these models assume a known revenue or cost for each customer class and define the optimal threshold levels for rationing based on overall revenue maximization or cost minimization. Pibernik and Yadav [49] consider a model of capacity reservation, based on service-level objectives when long-term cost or revenue measures of each customer class are not available. Zenios *et al.* [50], in their model for allocating cadaveric kidneys among various patient segments, consider an objective function incorporating QALYs. Also, in most of these models, the customer segments are independent with no overlap. Optimal rationing of drugs at the clinics to achieve better public health outcomes will be based on customer segments that are defined by demographic and health characteristics (medical threshold e.g., CD4 count or severity of disease or income level, sex, age). This implies that their membership in a customer segment is itself dependent upon the rationing decision. Deo [51] considers such a model where a public health planner who wants to maximize the total expected QALYs over a long time horizon, creates the optimal rationing strategy for HIV/AIDS patients. The determination of future QALYs from the rationing decision is captured through a simple disease transmission model. Through numerical analysis he shows that a rationing policy that follows open enrollment with enforced prioritization of current patients out-performs rationing heuristics that are commonly used in practice.

Stock rationing and allocation problems in public health require a model which considers the long-term objective of maximizing public health outcomes (DALYs, QALYs) with disease models to understand the

impact of the rationing strategy on long-term disease progression. Better understanding of behavioral issues involved in rationing health commodities is also needed for the rationing models to be put into practice.

CONCLUSION

This article presents an overview of the use of OR in public health in developing countries by first introducing the objective functions and output metrics commonly used by public health decision makers. A discussion of DALY and QALY metrics reveals that although they are commonly used in OR models for public health, their design is not flawless. The simple Ross and Macdonald model of disease transmission applied to malaria illustrates that resource allocation problems in OR need basic understanding of disease transmission. The concept of distribution equity is key to many public health OR problems and besides simple max–min formulations, commonly used measures of inequity such as the Gini coefficient and concentration curve are also required in many public health OR models. The number and scope of OR models for public health in developing countries continues to grow as work in this field continues apace. Understanding the main needs for OR in developing country public health programs and working closely with implementation partners are crucial for the OR/MS practitioner. Application areas of OR/MS in developing country health programs are highlighted along with opportunities for future research in this area.

INTRODUCTION

We consider mixed integer programs (MIPs) of the form

$$\min \left\{ \sum_{j \in N} c_j x_j \mid \sum_{j \in N} A_j x_j = d, x_j \in \mathbb{Z}_+ \right. \\ \left. \forall j \in I, x_j \in \mathbb{R}_+ \forall j \in C \right\} \quad (1)$$

where $N = \{1, \dots, n\}$, (I, C) forms a partition of N , $d \in \mathbb{Z}^m$, $A_j \in \mathbb{Z}^m$, and $c_j \in \mathbb{R} \forall j \in N$. We refer to the optimization problem obtained by relaxing the condition $x_j \in \mathbb{Z}_+$ to $x_j \in \mathbb{R}_+$ as the linear programming (LP) relaxation of problem (1). A fundamental problem in the design of cutting-planes and LP-based branch-and-cut algorithms is the derivation of valid inequalities for problem (1). This problem is particularly difficult for MIPs without special structure. The group approach is a method to generate cutting-planes for such problems. This approach requires that, any time a cutting-plane is generated, an optimal solution of the LP relaxation and a corresponding simplex tableau are known. Cuts are then generated using the information contained in one or several rows of this tableau.

As an illustration, consider

$$\min \left\{ -x_1 \mid -x_1 + 2x_2 \leq 4, 2x_1 - x_2 \leq 6, \right. \\ \left. 6x_1 + 5x_2 \leq 38, (x_1, x_2) \in \mathbb{Z}_+^2 \right\} \quad (2)$$

which can be put in the form of problem (1) by adding (integer) slack variables x_3, x_4 , and x_5 . The feasible region of problem (2) and its LP relaxation are represented in Fig. 1a. The optimal solution $x^{\text{LP}} = (4.25, 2.5)$ of the LP relaxation is highlighted with a star. The corresponding simplex tableau is

$$\begin{aligned} \min & -\frac{68}{16} + \frac{5}{16}x_4 + \frac{1}{16}x_5 \\ \text{s.t. } & x_1 + \frac{5}{16}x_4 + \frac{1}{16}x_5 = \frac{68}{16} \\ & x_2 - \frac{6}{16}x_4 + \frac{2}{16}x_5 = \frac{40}{16} \\ & x_3 + \frac{17}{16}x_4 - \frac{3}{16}x_5 = \frac{52}{16} \end{aligned} \quad (3)$$

where $B = \{1, 2, 3\}$ and $N = \{4, 5\}$ are the sets of indices of basic and nonbasic variables respectively.

We now describe how the group approach derives a cut for problem (2) from simplex tableau (Eq. 3). To this end, we consider the relaxation of problem (2) obtained by ignoring the restriction that basic variables x_1, x_2 , and x_3 are nonnegative but maintaining the restriction that they are integer. This relaxation K is described in the space of nonbasic variables (x_4, x_5) as

$$\begin{aligned} \min & -\frac{68}{16} + \frac{5}{16}x_4 + \frac{1}{16}x_5 \\ \text{s.t. } & \frac{5}{16}x_4 + \frac{1}{16}x_5 \equiv \frac{4}{16} \pmod{1} \\ & \frac{10}{16}x_4 + \frac{2}{16}x_5 \equiv \frac{8}{16} \pmod{1} \\ & \frac{1}{16}x_4 + \frac{13}{16}x_5 \equiv \frac{4}{16} \pmod{1} \\ & x_4 \in \mathbb{Z}_+, x_5 \in \mathbb{Z}_+ \end{aligned} \quad (4)$$

where the effect of integer variables x_1, x_2 , and x_3 is emulated by the “modulo 1” expression. The relaxation (Eq. 4) of problem (2) is itself an MIP for which facet-defining inequalities can be derived. We represent the set K of solutions (x_4, x_5) that satisfy the constraints of problem (4)

Figure 1. Feasible region of Equation (2) and corner relaxation.

with thicker bullets in the Fig. 1b. From this illustration, it can be verified that $(K) = \{(x_4, x_5) \in \mathbb{R}^2 \mid x_4 + x_5 \geq 4, x_4 \geq 0, x_5 \geq 0\}$. Substituting slack definitions for x_4, x_5 , we obtain the following description of the corner relaxation in the space of original variables $\{(x_1, x_2) \in \mathbb{R}^2 \mid 2x_1 - x_2 \leq 6, 6x_1 + 5x_2 \leq 38, 2x_1 + x_2 \leq 10\}$, which is represented in Fig. 2a. Because the basic solution associated with problem (3) is nondegenerate, relaxation (Eq. 4) can be graphically visualized as the set of integer solutions in the cone formed by the active constraints at x^{LP} . For this reason, it is often referred to as *corner relaxation* of problem (2) associated with basis B . It is clear that valid inequalities for problem (4) are also valid for problem (2) since problem (4) is a relaxation of problem (2).

As far as cutting-planes algorithms are concerned, we see in Fig. 2a that $2x_1 + x_2 \leq 10$ is a valid inequality for problem (2) that cuts off x^{LP} . More generally, nontrivial facets of the corner relaxation always yield violated cutting-planes when used in a simplex tableaux whose basic solutions are fractional. After adding $2x_1 + x_2 \leq 10$ to problem (2), we observe in Fig. 2b that the improved formulation still does not give the convex hull of feasible solutions to problem (2). However, its LP relaxation produces an optimal solution to problem (2).

In the previous example, it was simple to obtain a cut since the corner relaxation only had the two variables (x_4, x_5) . For more general cases, the above approach will only be effective if the inequalities describing the convex hull of K can be easily characterized. To obtain such a simple characterization, we

Figure 2. Corner relaxation and cutting-plane.

introduce a suitable set of new variables in the problem. In the case of problem (4), we study

$$\left\{ z \in \mathbb{Z}_+^{16 \times 16 \times 16} \mid \sum_{i=0}^{15} \sum_{j=0}^{15} \sum_{k=0}^{15} \frac{1}{16} \binom{i}{j}{k} z_{i,j,k} \equiv \frac{1}{16} \binom{4}{8}{4} \pmod{1} \right\} \quad (5)$$

where a variable z_g is introduced for each element g of the group $(G, +)$ where $G = C^{16} \times C^{16} \times C^{16}$ with $C^{16} = \{0, \frac{1}{16}, \frac{2}{16}, \dots, \frac{15}{16}\}$ and where the addition is taken modulo 1. It is clear that problem (5) is a relaxation of problem (4) since problem (4) can be obtained from problem (5) by fixing all variables z_g to 0 except for $z_{5,10,1}$ (which corresponds to x_4) and

$z_{1,2,13}$ (which corresponds to x_5). The advantage of problem (5) over problem (4) is that it applies to all simplex tableaux, whose entries are integer multiples of $\frac{1}{16}$ and whose right-hand sides are equal to $(\frac{4}{16}, \frac{8}{16}, \frac{4}{16})' \pmod{1}$ instead of applying only to problem (4). For this reason, this set is typically referred to as *master corner relaxation* of problem (3) and its convex hull is referred to as *master corner polyhedron* associated with problem (3). It is remarkable that, although the facetial structure of MIPs is typically complex, the facets of master corner polyhedra have a simple structure. Further, it can be shown that all facet-defining inequalities of the corner relaxation can be obtained from facet-defining inequalities of master corner relaxations; see Theorem 4.

The group-theoretic approach to MIP is the study of how corner (and more generally master corner) relaxations can be used to solve MIPs. Since corner relaxations are indeed relaxations of MIPs, they have been used both as a source of cutting-planes for MIPs and as a substitute for LP relaxations in branch-and-bound procedures; see Ref. 1 for a more detailed presentation. This article focuses solely on cutting-planes.

HISTORY

In 1958, Gomory [2] described the outline of the first finitely convergent cutting-planes algorithm for bounded MIP; see also Ref. 3. This algorithm successively generates cutting-planes to expose an optimal solution of the problem. The approach was later generalized to the mixed integer case [4]. Although the cuts central to this algorithm are group-theoretic cuts, they were not derived as such. The common principles underlying their derivation was discovered later. In fact, in a series of papers [5–7], Gilmore and Gomory studied how to solve cutting stock problems by column generation. While studying the solution of the integer knapsack problems that were required to solve their pricing problem, the authors discovered a periodic behavior to optimal solutions. The analysis of this behavior led Gomory to develop an asymptotic theory of MIP and to introduce corner and master corner polyhedra [8–10]. Following its formal introduction in Ref. 10, the group-theoretic approach for the generation of cutting-planes in MIP experienced a flurry of activities in the early 1970s. Gomory and Johnson [11,12] extended the theory to different types of groups. In particular, they studied infinite groups that are easier to use in practice, but are more difficult to study theoretically. The approach was further generalized by Johnson [13], who also considered in Ref. 14 models where constraints are imposed on basic variables. Johnson also investigated relationships to duality; see Ref. 15 for an exposition.

Early experiments with the Gomory cutting-planes algorithm concluded that,

although theoretically convergent, the algorithm did not often yield optimal solutions because it was prone to numerical problems. As a result, group cuts remain largely unused in computer implementations. A dramatic revival of interest occurred in the mid-1990s following the study [16] where Gomory mixed integer cuts (GMICs) were first shown to be useful in computation. GMICs were subsequently incorporated in all major commercial software. In 2003, new results and insights were presented in Refs 17 and 18. These papers provided a new impetus in the study of group problems. In particular, new extreme inequalities were developed for both finite and infinite group problems with a single constraint [19–22]; extreme inequalities were developed for group problems with multiple constraints [23,24]; the computational potential and quality of group cutting-planes was evaluated [25,26] and the strength of the corner relaxation was analyzed [27]. Most of this research focused on the “traditional” group framework in which integer variables are prevalent. In the last few years, however, a new stream of research has emerged that considers group problems in which all nonbasic variables are continuous [28]. This model and its variations have been vigorously investigated [29–33]. In particular, their study reveals interesting connections between group cutting-planes and intersection cuts from lattice-free convex sets.

VALID INEQUALITIES FROM GROUP RELAXATIONS

Corner and Master Corner Relaxations

We now introduce the notion of corner and master corner relaxation (or *group relaxation*) more precisely. We assume that the LP relaxation of problem (1) is feasible and bounded so that there is a basic feasible solution that is optimal. Let B and N represent the set of indices of basic and nonbasic variables respectively. Let A_B (respectively A_N) be the matrix whose columns correspond to the variables x_i for $i \in B$ (respectively $i \in N$). The optimal simplex tableau of the LP relaxation associated with B can be written as

$$x_B + A_B^{-1}A_N x_N = A_B^{-1}d. \quad (6)$$

The corner relaxation is obtained by relaxing the nonnegativity on basic variables x_B . For a tableau row in which the basic variable is continuous, relaxing the lower bound on the basic variable is equivalent to dropping the constraint. Therefore, we may assume without loss of generality that $B \cap C = \emptyset$. For the remaining tableaux rows in which basic variables are integer, relaxing lower bound on the basic variable amounts to requiring that the nonbasic variables satisfy the modular relation $A_B^{-1}A_N x_N \equiv A_B^{-1}d \pmod{1}$. The corner relaxation associated with B can then be defined as the set of solutions $(x_{N \cap I}, x_{N \cap C}) \in \mathbb{Z}_+^{|N \cap I|} \times \mathbb{R}_+^{|N \cap C|}$ that satisfy

$$A_B^{-1}A_N x_N \equiv A_B^{-1}d \pmod{1}. \quad (7)$$

In Equation (7), computation is carried in the group $(I^m, +)$ of real vectors whose components are in $[0, 1)$ and where the addition is taken modulo 1.

In order to obtain master corner relaxations (or group relaxations), we perform two additional steps. In the first step, we aggregate “duplicate” variables. In particular, we aggregate all integer variables whose columns in Equation (7) are identical modulo 1. We denote the set of all remaining columns by G^* . Similarly, we aggregate all continuous variables whose columns in Equation (7) are a positive multiple of each other. We also perform a normalization of the remaining columns so that they belong to the boundary S^m of the hypercube $\mathcal{H} = [-1, 1]^m$. We denote the set of all these columns by S^* . In the second step, we insert Equation (7) into a higher-dimensional space by adding variables. To this end, we identify a group $(G, +)$, where the addition is taken modulo 1 that is such that $G^* \subseteq G$. Similarly, we select a subset S of S^m that is such that $S^* \subseteq S$. Adding a variable for each element of G and each element of S yields the following definition where $\mathcal{F}$ is the function that associates to each real vector, the vector of its fractional parts and where $r = A_B^{-1}d \pmod{1}$.

Definition 1. Given $r \in I^m \setminus \{0\}$, a subgroup G of I^m , and a subset S of S^m , we define the mixed integer group problem, $\Gamma(G, S, r)$ to be the set of all functions $z : G \rightarrow \mathbb{R}$ and $y : S \rightarrow \mathbb{R}$ that satisfy the following properties:

1. $\sum_{g \in G} gz(g) + \mathcal{F}(\sum_{s \in S} sy(s)) = r$,
2. $z(g) \in \mathbb{Z}_+ \quad \forall g \in G$,
3. $y(s) \in \mathbb{R}_+ \quad \forall s \in S$,
4. z and y have finite supports.

In Definition 1, $z(g)$ and $y(s)$ are, respectively, the integer and continuous variables of the group relaxation. Condition 1 represents the defining equality of the master corner relaxation constructed from the simplex tableau. We refer to a problem for which there are m constraints in Condition 1 as being an m -dimensional mixed-integer group problem. Condition 4 is assumed to guarantee that the summation in Condition 1 is well defined. In Definition 1, we also implicitly assume that S is chosen in such a way that $\Gamma(G, S, r) \neq \emptyset$.

There are many possible choices for G in Definition 1. Assuming that the determinant of the basis matrix A_B is D , one could select the group $(G, +)$ such that $G = C^D \times \dots \times C^D$ and $C^D = \{0, \frac{1}{D}, \dots, \frac{D-1}{D}\}$. In this case, $\Gamma(G, S, r)$ is referred to as a *finite group problem*. Further, $(G, +)$ can always be chosen to be $(I^m, +)$. In this case, $\Gamma(G, S, r)$ is referred to as an *infinite group problem*. Similarly, there are many possible choices for S . It is typically chosen to be the empty set if cuts for pure integer programs are desired or chosen to be S^m otherwise. In the remainder of this article, we often use G and I^m to represent the groups $(G, +)$ and $(I^m, +)$, respectively.

Cuts from Group Relaxations

Although unusual in appearance, $\Gamma(G, S, r)$ is an MIP that is a relaxation of problem (1). As our ultimate goal is to generate valid inequalities for problem (1) from this relaxation, we now focus on characterizing strong valid inequalities for $\Gamma(G, S, r)$.

Figure 3. Gomory mixed integer cut.

Valid Inequalities. In order to describe a valid inequality, we must associate a coefficient $\alpha(g)$ to each integer variable $z(g)$ and associate a coefficient $\beta(s)$ to each continuous variable $y(s)$. For this reason, valid inequalities are often defined and represented as functions over G and S , respectively (Fig. 3). We then define the notion of valid inequality as one that is satisfied by all solutions of the problem.

Definition 2. Given $r \in I^m \setminus \{0\}$, a subgroup G of I^m and a subset S of S^m , we say that the functions $\alpha : G \rightarrow \mathbb{R}_+$ and $\beta : S \rightarrow \mathbb{R}_+$ define a valid inequality for $\Gamma(G, S, r)$ if $\sum_{g \in G} \alpha(g)z(g) + \sum_{s \in S} \beta(s)y(s) \geq 1$, $\forall (z, y) \in \Gamma(G, S, r)$, where $\alpha(o) = 0$.

Definition 2 does not include the trivial inequalities $z(g) \geq 0$ and $y(s) \geq 0$ as they do

not yield violated cutting-planes for MIPs. It focuses on nontrivial inequalities that can be rescaled to have right-hand sides equal to 1. Definition 2 requires that the coefficients of the variables are nonnegative in any valid inequality, which is without loss of generality when G is finite. Although Definition 2 does not require that $\alpha(r) = 1$, we assume implicitly that $\alpha(r) = 1$ in valid inequalities whenever $r \in G$.

Subadditive Inequalities. The concept of valid inequality does not intrinsically carry a notion of strength. The following concept of subadditive inequality identifies, among valid inequalities, those that support $\Gamma(G, S, r)$. The definition is taken from Ref. 13, although variants appeared earlier in Refs 10–12.

Definition 3. A valid inequality for $\Gamma(G, S, r)$ is said to be a subadditive valid inequality for $\Gamma(G, S, r)$ if it satisfies the following requirements:

1. $\alpha(g_1) + \alpha(g_2) \geq \alpha(g_1 + g_2), \forall g_1, g_2 \in G$
2. $\alpha(g_1) + \sum_{s \in S} \beta(s)y(s) \geq \alpha(g_2), \forall g_1, g_2 \in G$ and $\forall y$ with finite support s.t. $g_1 + \mathcal{F}(\sum_{s \in S} sy(s)) = g_2$;
3. $\sum_{s_1 \neq s_2} \beta(s_1)y(s_1) \geq \beta(s_2), \forall y$ with finite support s.t. $s_2 = \sum_{s_1 \neq s_2} s_1 y(s_1)$ and $\sum_{s_1 \neq s_2} s_1 y(s_2) \in S$.

It is proven in Ref. 11 that valid inequalities for master group problems are dominated by subadditive inequalities. Therefore, when deriving strong inequalities for $\Gamma(G, S, r)$, it is sufficient to study subadditive inequalities. Definition 3 is often cumbersome to verify. However, when dealing with group relaxations with only integer variables, that is, $S = \emptyset$, it reduces to verifying Condition 1. For piecewise linear functions, necessary and sufficient conditions have been developed to help show that Condition 1 holds [18, 22, 24].

Minimal Inequalities. A natural strengthening of the concept of subadditive inequality occurs when requiring that the inequality is not dominated coefficient-wise by another valid inequality. In the context of the group problem, such inequalities are said to be *minimal*. A general characterization of minimal inequalities of $\Gamma(G, S, r)$ is given in Ref. 13 that extends the more specific results given in Refs [10–12]. Since this characterization is technical, we restrict its presentation to two particular cases that are commonly encountered and are simpler to describe. The first is for finite group problems that have only integer variables.

Theorem 1. Given $r \in G \setminus \{o\}$, a finite subgroup G of I^m and a valid inequality α for $\Gamma(G, \emptyset, r)$, α is a minimal valid inequality if and only if

1. $\alpha(g_1) + \alpha(g_2) \geq \alpha(g_1 + g_2), \forall g_1, g_2 \in G$
2. $\alpha(g) + \alpha(r - g) = \alpha(r), \forall g \in G$.

When continuous variables are involved, the coefficients β of continuous variables must be related to the slope of the function α at the origin in the direction of the constraints coefficients of these variables.

Theorem 2. Given $r \in I^m \setminus \{o\}$, a subset S of S^m and an inequality (α, β) for $\Gamma(I^m, S, r)$, the inequality (α, β) is minimal for $\Gamma(I^m, S, r)$ if and only if the following conditions hold:

1. $\alpha(g_1) + \alpha(g_2) \geq \alpha(g_1 + g_2), \forall g_1, g_2 \in I^m$
2. $\beta(s) = \lim_{h \rightarrow 0} \frac{\alpha(\mathcal{F}(hs))}{h}, \forall s \in S$
3. $\alpha(g) + \alpha(r - g) = 1, \forall g \in I^m$.

When an inequality is known to be subadditive, verifying that it is minimal reduces to establishing that it satisfies Conditions 2 and 3. This verification is typically direct.

Extreme Inequalities. Although a minimal inequality is not dominated coefficient-wise by any other single valid inequality, it might be dominated coefficient-wise by a convex combination of other valid inequalities. This motivates the following definition.

Definition 4. Given a valid inequality (α, β) for $\Gamma(G, S, r)$, we say that it is extreme for $\Gamma(G, S, r)$ if whenever $\alpha = \frac{1}{2}\alpha^1 + \frac{1}{2}\alpha^2$ and $\beta = \frac{1}{2}\beta^1 + \frac{1}{2}\beta^2$ for some valid inequalities (α^1, β^1) and (α^2, β^2) of $\Gamma(G, S, r)$ then $\alpha = \alpha^1 = \alpha^2$ and $\beta = \beta^1 = \beta^2$.

It is shown in Ref. 13 that extreme valid inequalities for $\Gamma(G, S, r)$ are minimal for $\Gamma(G, S, r)$. Therefore, it is sufficient to search for extreme inequalities among minimal inequalities. We next describe important results regarding extreme inequalities. We differentiate the finite and infinite cases.

When the group G used in $\Gamma(G, S, r)$ is finite, there is an elegant characterization of the extreme inequalities of $\Gamma(G, S, r)$. In this case, the function $\alpha(\cdot)$ can be represented as a vector with $|G|$ entries that we denote as α_g . Only vectors satisfying the conditions of Theorem 1 correspond to minimal inequalities. Among them, only those that are not convex combinations of one another can be extreme. This leads to the following theorem of Gomory [10].

Theorem 3. Given $r \in G \setminus \{o\}$ where G be a finite subgroup of I^m , the extreme inequalities of $\Gamma(G, \emptyset, r)$ are $z_g \geq 0$ for $g \in G$ and $\sum_{g \in G} \alpha_g z_g \geq 1$ where $\alpha \in \mathbb{R}_+^{|G|}$ are the extreme points of $\Gamma^*(G, \emptyset, r)$, where

$$\Gamma^*(G, \emptyset, r) = \left\{ \alpha \in \mathbb{R}_+^{|G|} \left| \begin{array}{ll} \alpha_{g_1} + \alpha_{g_2} \geq \alpha_{g_1+g_2}, & \forall g_1, g_2 \in G \\ \alpha_g + \alpha_{r-g} = \alpha_r, & \forall g \in G \\ \alpha_r = 1, \\ \alpha_g \geq 0, & \forall g \in G \end{array} \right. \right\}.$$

Proving that an inequality α is extreme using Theorem 3 is conceptually simple as it reduces to proving that the vector of its coefficients yields an extreme point of $P^*(G, \emptyset, r)$. Given an extreme inequality of a master corner relaxation, one can create a valid inequality for its initial corner relaxation by setting all the coefficients of introduced variables to zero. Gomory [10] shows that all extreme inequalities for a corner relaxation can be obtained in this way.

Theorem 4. All extreme inequalities of a corner relaxation can be obtained from the extreme inequalities of its finite master group relaxations.

When the group G used in $\Gamma(G, S, r)$ is infinite, the situation is more complex. The first proof that a given inequality is extreme was described in Ref. 12 for piecewise linear subadditive inequalities with two slopes. Streamlined arguments were proposed in a slightly different framework in Ref. 17. Variants can also be found in Refs 24 and 34. These proofs are typically constructed using contradiction as follows. A subadditive minimal inequality α is considered and is assumed to not be extreme. In this case, $\alpha = \frac{1}{2}\alpha_1 + \frac{1}{2}\alpha_2$ where $\alpha_1 \neq \alpha_2$ and α_1, α_2 are minimal valid inequalities for $\Gamma(I^m, \emptyset, r)$. The “equality” set $E(\alpha) = \{(g_1, g_2) \in I^m \times I^m \mid \alpha(g_1) + \alpha(g_2) = \alpha(g_1 + g_2)\}$ is then constructed. Since α_1 and α_2 are minimal functions, they are subadditive. Thus $E(\alpha_1) \supseteq E(\alpha)$ and $E(\alpha_2) \supseteq E(\alpha)$. The final contradiction is then obtained by showing that if $\alpha_1(g_1) + \alpha_1(g_2) = \alpha_1(g_1 + g_2)$ for all $g_1, g_2 \in E(\alpha)$, then $\alpha_1 = \alpha$. The proof that this equality holds is typically done by considering various intervals over which

a type of result called *Interval Lemma* is invoked [17,24,34]. We refer the reader to Ref. 1 for a more detailed description of the approach. This approach is well suited for proving that piecewise linear subadditive inequalities are extreme. We mention, however, that not all extreme inequalities of infinite group problems are piecewise linear [35].

Extreme inequalities of group relaxations can be applied to simplex tableaux in the manner illustrated in the section titled “Introduction.” Because extreme inequalities for one-dimensional group problems are easiest to describe, all but one row of the simplex tableau are typically relaxed before a group cut is generated. Among extreme inequalities for one-dimensional group problems, the GMIC is particularly significant as it is probably the simplest function that satisfies the conditions of Theorems 1 and 2 and is also the most important computationally as seen in the section titled Computational Potential of Group Cuts.

Theorem 5. Let G be a subgroup of I^1 . The GMIC $\alpha(g) = \min\{\frac{g}{r}, \frac{1-g}{1-r}\}$ is extreme for $\Gamma(G, \emptyset, r)$.

In Fig. 3, we represent the GMIC for C^{15} and I^1 when $r = \frac{4}{15}$. In this figure, we represent the elements g of the groups C^{15} and I^1 on the x axis. The values of $\alpha(g)$ are represented on the y axis with dots for C^{15} and with a solid line for I^1 .

OBTAINING STRONG/EXTREME INEQUALITIES FOR GROUP PROBLEMS

We now address the problem of deriving strong cuts for group problems. In the section titled “Relations between Extreme Inequalities,” we describe how to use the extreme inequalities of a group problem to generate extreme inequalities for other group problems. In the section titled “Constituent Functions,” we present methods to generate extreme inequalities *ab nihilo*. These inequalities are the building blocks used by other procedures.

Relations between Extreme Inequalities

We now discuss relations between the extreme inequalities of various group problems.

From Infinite Group Problems. We assume in this section that we know an extreme inequality α for $\Gamma(I^m, \emptyset, r)$. When $m = 1$, inequality α can typically be used to create extreme inequalities for finite group problems as follows [11,12].

Theorem 6. *Given an extreme function $\alpha : I^1 \rightarrow \mathbb{R}_+$ for $\Gamma(I^1, \emptyset, r)$ that is continuous and piecewise linear, and a finite cyclic subgroup G of I^m where G contains all the points at which α is nondifferentiable, the function obtained by restricting α to G is extreme for $\Gamma(G, \emptyset, r)$.*

Strong inequalities for $\Gamma(I^m, \emptyset, r)$ can also be used to generate strong inequalities for other infinite group problems as the following results suggest [13,24].

Theorem 7. *Given a surjective map $\varsigma : G_1 \rightarrow G_2$ that is a homomorphism, the function α is subadditive and minimal for $\Gamma(G_1, \emptyset, r)$ if and only if the function $\alpha(\varsigma(x))$ is subadditive and minimal for $\Gamma(G_2, \emptyset, v)$, for any v such that $\varsigma(v) = r$.*

For particular types of homomorphisms, Theorem 7 can be strengthened. Given $n_i \neq 0$ for $i = 1, \dots, m$, we define the multiplicative homomorphism $\lambda : I^m \rightarrow I^m$ as $\lambda(x) = (n_1x_1, n_2x_2, \dots, n_mx_m)$.

Theorem 8. *Given a multiplicative homomorphism λ , the function α is extreme for $\Gamma(I^m, \emptyset, r)$ if and only if $\alpha \circ \lambda$ is extreme for $\Gamma(I^m, \emptyset, v)$, where $\lambda(v) = r$.*

Theorem 7 can also be strengthened if the homomorphism ς is an automorphism [13].

Theorem 9. *Given an automorphism ω of I^m and an extreme inequality α of $\Gamma(I^m, \emptyset, r)$, the function $\alpha \circ \omega$ is extreme for $\Gamma(I^m, \emptyset, \omega^{-1}(r))$.*

Combination procedures can also be used to generate extreme inequalities. In particular, one can “aggregate” the rows of a group problem into a single constraint before applying a one-dimensional group cut. More precisely, let $\alpha : I^1 \rightarrow \mathbb{R}_+$ be a valid inequality for $\Gamma(I^1, \emptyset, r)$ and let $\lambda = (\lambda_1, \dots, \lambda_m) \in \mathbb{Z}^m$ be weights chosen so that $\lambda \neq 0$. The aggregation function $\alpha^\lambda : I^m \rightarrow \mathbb{R}_+$ is defined as $\alpha^\lambda(x) = \alpha(\sum_{i=1}^m \lambda_i x_i)$. When the inequality α is known to be extreme for $\Gamma(I^1, \emptyset, r)$, $\alpha^\lambda(x)$ can be shown to be extreme in a variety of contexts [24,34,36].

Another such combination procedure is *sequential-merge*. This procedure generates an inequality α^1 for $\Gamma(I^{m+1}, \emptyset, r)$ by combining an inequality α^2 for $\Gamma(I^m, \emptyset, r)$ with an inequality α^3 for $\Gamma(I^1, \emptyset, r)$. Intuitively, the procedure applies α^2 to the first m rows of $\Gamma(I^{m+1}, \emptyset, r)$, aggregates the resulting inequality with the last row of $\Gamma(I^{m+1}, \emptyset, r)$, and applies α^3 to the aggregate constraint. Under some mild conditions [23,37], α^1 can be shown to be extreme for $\Gamma(I^{m+1}, \emptyset, r)$ if α^2 and α^3 are extreme for $\Gamma(I^m, \emptyset, r)$ and $\Gamma(I^1, \emptyset, r)$, respectively.

From Finite Group Problems. We assume in this section that we know an extreme inequality α for $\Gamma(G, S, r)$, where G is a finite group. Theorems 10 and 11 are due to Gomory [10] and relate extreme inequalities of finite group problems.

Theorem 10. *Given two finite subgroups G^1 and G^2 of I^m , $r \in G^1 \setminus \{o\}$ and a surjective homomorphism $\varsigma : G^1 \rightarrow G^2$, the inequality $\alpha \circ \varsigma$ is extreme for $\Gamma(G^1, \emptyset, r)$ whenever $\alpha : G^2 \rightarrow \mathbb{R}_+$ is an extreme inequality for $\Gamma(G^2, \emptyset, \varsigma(r))$ and $r \notin \text{Kern}(\varsigma)$.*

Theorem 11. *Given an automorphism $\omega : G \rightarrow G$, the inequality ϕ is extreme for $\Gamma(G, \emptyset, r)$ if and only if $\phi \circ \omega$ is extreme for $\Gamma(G, \emptyset, \omega^{-1}(r))$.*

Interpolation is a natural idea to create inequalities for infinite group problems from finite group problems. Interpolation, however, does not necessarily create extreme inequalities for $\Gamma(I^m, \emptyset, r)$ even in the

case where $m = 1$, a situation where the interpolation is unique. We refer to Ref. 34 for a discussion. A stronger procedure to generate inequalities for infinite group problems from finite group problems is *fill-in*. Fill-in has its origin in Ref. 12 and is described in its generality in Ref. 13. This procedure is analogous to lifting. Let G be a subgroup of I^m and $S \subseteq S^m$ and assume that S is sufficiently diverse that every vector $s \in \mathbb{R}^m$ can be written as a nonnegative combination of elements of S . Let (α, β) be a valid subadditive function for $\Gamma(G, S, r)$. To obtain a valid subadditive inequality $(\hat{\alpha}, \hat{\beta})$ for $\Gamma(I^m, S^m, r)$, we use the following procedure. First, we construct $\tilde{\beta}(s) = \min \{ \sum_{s' \in L} \beta(s')y(s') \mid s = \sum_{s' \in L} s'y(s'), y(s') \geq 0 \}$ where L is a linearly independent subset of S . Then we construct the function $\hat{\beta} : \mathbb{R}^m \rightarrow \mathbb{R}_+$ as $\hat{\beta}(s) = \lambda \tilde{\beta}(s')$ where $s' \in S^m$, $\lambda \geq 0$, and $s = \lambda s'$. In other words, $\hat{\beta}$ is the homogenous extension of $\tilde{\beta}$ to $\mathbb{R}^m$. Finally, we compute $\hat{\alpha}(g) = \min \{ \alpha(g') + \hat{\beta}(s) \mid g' \in G, s \in S, g' + \mathcal{F}(s) = g \}$.

For group problems with a single constraint, the fill-in procedure produces inequalities that have two slopes and are therefore extreme [12]. For group problems with multiple constraints, however, the inequality can typically only be proven to be subadditive even if an extreme inequality is used as a starting point of the procedure. Sufficient conditions for fill-in inequalities to be extreme are given in Refs 31 and 38.

Constituent Functions

Finite Group Problems. For discrete problems, deriving a violated group-theoretic inequality reduces to solving an LP over Gomory's characterization; see Theorem 3. The solution of this LP might be computationally demanding if the size of the group is large. As a result, families of extreme points of $\Gamma^*(G, \emptyset, r)$, which result in extreme inequalities for finite group relaxations, are typically derived analytically. The inspiration for the derivation of these families inequalities come either from an analytical study of its structure or from shooting experiments [18] where a random objective is optimized over $\Gamma^*(G, \emptyset, r)$ and the pattern of the resulting inequality is

studied and generalized. Such analyses have produced many families of inequalities including two- and three-slope functions [10,39]. A form of lifting called *tilting* has also been used to derive families of extreme inequalities from lower-dimensional faces of finite group problems [39]. Obtaining the extreme inequalities of simple subfamilies of subadditive functions has also been proposed as a way to obtain strong inequalities for group problems in Refs 21 and 22, where the procedure is coined *approximate lifting*.

Infinite Group Problems. Generating families of extreme inequalities for infinite group problems is harder as it is not possible to use shooting experiments. Many known extreme inequalities for infinite group problems are interpolations of extreme inequalities for finite group problems [17,21]. The approximate lifting procedure of Miller *et al.* and Richard *et al.* [21,22] also yields candidate extreme inequalities.

Extreme inequalities for infinite group problems can also be derived from simple sets. In this approach, a simple mixed integer set F with free integer variables and at least a continuous variable is considered. An aggregation scheme is then derived that aggregates the group problem variables into the variables of F . Any strong inequality for F can then be converted into a group-theoretic cut using the previously obtained aggregation scheme. This procedure is successfully used in Refs 19 and 40 and also provides an alternate derivation of GMIC in Ref. 41.

A new direction of research that has attracted much attention over the past few years is the derivation of strong inequalities for *continuous group problems*, that is, problems of the form $\Gamma(\{o\}, S, r)$ for which it is typically not assumed that $S \subseteq S^m$. A likely reason for this interest is that valid inequalities for $\Gamma(\{o\}, S, r)$ have a strong geometrical grounding. To describe it, we define a full-dimensional convex set P in $\mathbb{R}^m$ to be a lattice-free convex set if $\text{int}(P) \cap Z^m = \emptyset$. Further, we assume that P is a maximal lattice-free set if there does not exist another lattice-free convex set P' such that $P' \neq P$ and $P' \supseteq P$. It is shown in Ref. 29 that nontrivial minimal valid

inequalities for $\Gamma(\{o\}, \mathbb{R}^m, r)$ are equivalent either to $\beta(s) \geq 0$ or to $\sum_{s \in \mathbb{R}^m} \beta(s)y(s) \geq 1$, where the set $P(\beta) = \{u \in \mathbb{R}^m \mid \beta(u+r) \leq 1\}$ is a maximal lattice-free set with $-r$ in its interior. The study of minimal inequalities for these sets therefore reduces to the study of maximal lattice-free convex sets. We refer to Refs 28,30,31,42, and 43 for discussions and mention that valid inequalities for $\Gamma(\{o\}, S, r)$ can be extended to $\Gamma(G, S, r)$ using the fill-in procedure described above [38].

COMPUTATIONAL POTENTIAL OF GROUP CUTS

Various recent studies have tried to gauge the strength of group cuts for MIPs. In particular, Fischetti and Monaci [27] evaluates the strength of corner relaxation on a family of test MIP problems. The authors find that the corner relaxation cuts a substantial fraction of the integrality gap of MIPs, especially for problems with integer variables that are not binary. This study therefore suggests that there is value in studying group-theoretic cuts for MIPs. An important question is therefore to determine which group cuts are most useful in solving MIPs.

Often, group cuts are generated from single rows of simplex tableaux. Among one-dimensional group cuts, GMIC is the most extensively used in commercial computer implementations; see Bixby and Rothberg [44]. Many other cuts, however, have been tested. They include two-step MIR (mixed integer rounding) inequalities [25,45], k -cuts (homomorphisms of GMIC) [46] and interpolated cuts [26]. The overwhelming conclusion of these studies is that GMICs are most effective among one-dimensional group-theoretic cuts. Several families of two-slope functions can also be helpful [25,45]. All other families of cuts seem to have a marginal impact when GMICs are also added [26].

While there might not be many practical reasons to derive further families of cuts for one-dimensional group problems, the investigation of cuts for group problems with multiple constraints is promising, as suggested in Ref. 27. In fact, very few strong

inequalities are known in this case, and multidimensional equivalents of GMIC are yet to be found. Experiments with the continuous group relaxation approach in Ref. 47 give empirical evidence that some multirow group cuts might be helpful in computation. Determining whether the computational potential of these cuts can be harnessed is an active area of research.

INFINITE HORIZON PROBLEMS

ARCHIS GHATE
University of Washington,
Seattle

INTRODUCTION

A typical discrete-time sequential decision problem involves a system whose state is assumed to evolve either deterministically or probabilistically over time-periods that are often called *stages*. This evolution is affected by the decisions a planner makes at the beginning of each stage after observing the system state. The decision maker's goal then is to optimize some measure of system performance over a certain time-horizon. For example, in a typical production and inventory management problem, the system state is given by the inventory on hand at the beginning of a stage, and the decision corresponds to the production level in that stage. The inventory beginning the next stage equals the old inventory plus the production quantity minus the stochastic demand filled. Unsatisfied demand may be lost. The planner's goal may be to maximize the expected total discounted profit, where revenue is generated by selling the product, and costs are incurred for production, inventory holding, and shortage.

The dynamic systems in such optimization problems often do not have a predetermined time of extinction. Thus, using a finite planning horizon typically introduces end-of-study effects on early decisions. Indeed, a finite horizon formulation of a production planning problem essentially amounts to assuming that the demand in all subsequent time-periods after this horizon is zero. Then the decision maker is likely to plan initial production such that the inventory ending this finite horizon is zero, forcing him/her to produce additional units later when the actual demand beyond the initial study horizon is

revealed. In fact, if the production costs in these later periods turn out to be high, the decision maker may realize rather late that it would have been optimal to produce more earlier on and carry inventory forward to later periods. More generally, finite horizon formulations of dynamic optimization problems can lead to short-sighted decisions, and therefore, infinite horizon versions of such problems are studied extensively.

The literature on infinite horizon optimization is vast and encompasses diverse fields including electrical engineering, especially control systems; economics/finance; operations research/management science; statistics; and mathematics. It spans both discrete as well as continuous-time problems, and includes research where the states and decisions may belong to abstract infinite-dimensional spaces. Here, we focus only on discrete-time models under the assumption that both the state and decision sets are finite because these appear to be more common in the operations research and management science literature (see Refs 1 and 2 for continuous-time and/or metric space extensions). Within this context, there are two somewhat distinct bodies of research—stationary models and nonstationary models.

A majority of the work assumes that the data do not change over time, leading to *stationary* infinite horizon problems. More specifically, stationary infinite horizon Markov decision problems (MDPs) with the expected total discounted reward criterion are the most studied and best understood among such models. Extensive theoretical and algorithmic treatments of such models along with their diverse applications as well as discussions of MDPs with other optimality criteria, and their continuous-time and semi-Markov extensions can be found in Refs 3–7; these will be reviewed in detail elsewhere.

A considerable amount of research on the other hand focuses on *nonstationary* infinite horizon problems. Here, we are

interested in truly nonstationary problems in contrast to problems in which data trends over time can be completely specified with a finite set of parameters. These problems present notoriously difficult challenges that are circumvented by (the time-homogeneity) assumption in stationary problems. While computing an optimal policy in a stationary infinite horizon MDP can be reduced to a finite-dimensional problem through Bellman's equations, a nonstationary problem is necessarily infinite-dimensional. Even in a deterministic nonstationary problem, computing only a first period decision that is infinite horizon optimal may require knowledge of an *infinite* number of data parameters, for example, a reward function for every time-period, rendering the task impossible. The question arises as to whether it is possible to forecast data parameters for only a finite number of periods N , and compute an N horizon optimal (with respect to these specific N period data parameters) first period decision that remains optimal for all infinite horizon problems no matter what future data parameters for periods $N + 1$ and beyond are revealed. A finite horizon with this property is called a *forecast horizon*. In short, when data parameters beyond period N are irrelevant to computing an infinite horizon optimal first period decision, N is a forecast horizon.

In the fortunate case where such a forecast horizon exists and can be discovered using a finite procedure, we could implement the corresponding first period decision and then roll forward to construct a new infinite horizon problem with a new initial state. The process could then be repeated recursively ad infinitum to deliver an infinite horizon optimal strategy. This rolling (or receding) horizon procedure renders the nonstationary infinite horizon problem "solvable." When such horizons fail to exist, it may be possible to obtain horizon-dependent bounds on the error induced by solving finite horizon truncations of the infinite horizon problem [8–10]. These ideas go at least as far back as early work on production planning problems in the 1950s [11–14]. Since then, a range of theoretical, algorithmic, and application-specific papers

in areas such as production planning and inventory management [15–28], equipment replacement [29–31], capacity expansion [32–35], research and development planning [36], and cash management [37] have appeared in the infinite horizon optimization literature. An extensive review of these works with a detailed classified bibliography of over two hundred articles is available in Ref. 38. Below we outline some of the main ideas in this field. We focus on discounted deterministic problems and only briefly mention extensions to their stochastic counterparts.

CHALLENGES IN NONSTATIONARY INFINITE HORIZON OPTIMIZATION

Owing to infinite data requirements, it is not in general possible even to completely specify an instance of a truly nonstationary infinite horizon problem. We must instead speak of a *class* Φ of nonstationary infinite horizon problems characterized by certain structural properties of their data parameters. For example, Φ could be the class of all discounted deterministic cost minimization production planning problems with stationary discount factors strictly less than one and the following cost and demand data properties: (i) linear production and inventory holding costs, (ii) strictly positive integer-valued unit production and unit inventory costs bounded above by given positive integers c and h respectively, and (iii) strictly positive integers-valued demands bounded above by a given positive integer d . For $N \geq 1$, let ϕ_N denote the data parameters for the first N periods from a forecast ϕ in Φ . For instance, in the above class of production planning problems, ϕ_N corresponds to specific values of discount factor $0 < \alpha < 1$, integer-valued unit production costs $0 < c_1, c_2, \dots, c_N \leq c$, integer-valued unit inventory holding costs $0 < h_1, h_2, \dots, h_N \leq h$, and integer demands $0 < d_1, d_2, \dots, d_N \leq d$. Let $\phi(N)$ be the set of all forecasts θ in Φ whose data parameters for the first N periods match that of ϕ , that is, $\theta_N = \phi_N$.

The idea of a forecast horizon can then be made more precise as follows: N is a *forecast*

horizon for ϕ if there exists a first period decision optimal to ϕ_N that remains optimal to all infinite horizon forecasts θ in $\Phi(N)$. According to this definition, the discovery that N is a forecast horizon can be made based on the knowledge of specific values of data parameters in the first N periods as well as on properties of class Φ ; it must however be made *without* any reference to ϕ . Such a forecast horizon could be viewed as a forecast horizon for all forecasts in $\Phi(N)$.

The weaker notion of a solution horizon arises when the class Φ is a singleton forecast ϕ : N is a *solution horizon* if a first period decision optimal to ϕ_N is also optimal to ϕ . Note here that whether N is a solution horizon for ϕ or not may depend on data parameters in ϕ in periods $N + 1$ and beyond, whereas this is not allowed in the definition of a forecast horizon.

A stronger notion is that of a forecast horizon for class Φ : N^* is a *forecast horizon for class Φ* if it is a forecast horizon for *every* ϕ in Φ . Hence, the conclusion that N^* is a forecast horizon for class Φ must be drawn based solely on the defining properties of Φ without reference to any specific data parameter values. Finally, if N^* is a forecast horizon for class Φ , then so are all horizons longer than N^* . Therefore, it is of some interest to find the *minimum* forecast horizon owing to the computational difficulties and costs involved in forecasting data parameters for the distant future. The above ideas also specialize to finite horizon problems [38]. See Refs 38–41 for complete formal details on forecast and solution horizons.

Five main sources of these horizons were identified in the classified bibliography in Ref. 38. These are (i) cost structure, (ii) constraints, (iii) discounting, (iv) turnpike properties, and (v) ergodicity. For instance, the relative value of fixed costs in relation to holding costs is an important factor in existence of forecast horizons in the dynamic lot-size model of Wagner and Whitin [14]. Nonnegativity and warehouse capacity constraints on inventory values lead to forecast horizons in the wheat-trading model of [42]. The turnpike property, well studied in the economics literature for a long time [43], can also lead to solution horizons [28,44,45]. This arises when

the problem horizon is sufficiently long with given initial and terminal states and an optimal trajectory quickly passes from the initial state to a steady-state, remains there for a long time, ultimately returning to the final state as late as possible. This is typical in maximization problems with concave objective functions and state dynamics functions. Chand *et al.* [38] comment that unfortunately researchers often do not explicitly identify the precise source of forecast and solution horizons as they result from complex interactions between several problem characteristics.

A portion of the literature over the years has attempted to establish general conditions for existence of solution and forecast horizons and on developing algorithms for their discovery. It is often easy to establish that for any forecast ϕ in class Φ , the finite horizon optimal values $v^*(\phi_N)$ converge to the infinite horizon optimal value $v^*(\phi)$ as $N \rightarrow \infty$. Uniqueness of an infinite horizon optimal solution $x^*(\phi)$ to a forecast ϕ is then sufficient for solution and forecast horizons for forecast ϕ to exist. See Refs 36, 41, 46–49 for detailed formal discussions of sufficiency of unique infinite horizon optima. Unfortunately, uniqueness is often impossible to verify and is especially rare in discrete optimization problems [1,49,50]. Researchers have thus attempted to instead establish convergence of sets of finite horizon optima to the set of infinite horizon optima and then have applied tie-breaking procedures to force solution convergence [1,49]. Here, we discuss an alternative approach that circumvents this issue for a class of problems where optimal first period decisions are monotone in horizon length—a property succinctly described as policy monotonicity.

EXPLOITING POLICY MONOTONICITY

We illustrate the main ideas in this type of work through a production planning example taken from Ref. 27. Let Φ be the class of all infinite horizon production planning problems with the following defining characteristics:

1. Non-negative integer demands.

2. *Convex* non-negative production cost functions where
 - the cost of not producing in a period is zero,
 - the marginal cost of production is at least $c > 0$,
 - the marginal cost of production is at most γ .
3. *Convex* nonnegative inventory holding cost functions where
 - the cost of not holding inventory is zero,
 - the marginal cost of holding is at least $h > 0$.
4. Discount factors fixed at $0 < \alpha < 1$.
5. Nonnegative initial inventory.
6. There exists at least one production-inventory schedule with finite total discounted infinite horizon cost.

Any specific forecast ϕ from this class results in the following infinite horizon production planning problem over time-periods $n = 1, 2, \dots$

$$\begin{aligned}
 (P^\phi) \quad & \min \sum_{n=1}^{\infty} \alpha^{n-1} [c_n^\phi(x_n) + h_n^\phi(i_n)] \\
 & i_0 \text{ given} \\
 & i_{n-1} + x_n - d_n^\phi = i_n, \quad n = 1, 2, \dots \\
 & x_n \geq 0, \quad n = 1, 2, \dots \\
 & i_n \geq 0, \quad n = 1, 2, \dots \\
 & x_n \text{ integer}, \quad n = 1, 2, \dots \\
 & i_n \text{ integer}, \quad n = 1, 2, \dots
 \end{aligned}$$

Here, $c_n^\phi(\cdot)$ and $h_n^\phi(\cdot)$ are production and inventory cost functions, $d_1^\phi, d_2^\phi, \dots$ is the demand stream, and i_0^ϕ is the initial inventory on hand, all specific to forecast ϕ in Φ . The production schedule is denoted $x_1, x_2, \dots$ and given the initial inventory and the demand stream, it induces the inventory schedule $i_1, i_2, \dots$. Note however that for a truly nonstationary problem, we can never entirely specify ϕ and therefore problem (P^ϕ) is only an abstract entity. We instead focus on its finite-horizon truncations

$(P^{\phi N})$:

$$\begin{aligned}
 (P^{\phi N}) \quad & \min \sum_{n=1}^N \alpha^{n-1} [c_n^\phi(x_n) + h_n^\phi(i_n)] \\
 & i_0 \text{ given} \\
 & i_{n-1} + x_n - d_n^\phi = i_n, \quad n = 1, 2, \dots, N \\
 & x_n \geq 0, \quad n = 1, 2, \dots, N \\
 & i_n \geq 0, \quad n = 1, 2, \dots, N \\
 & x_n \text{ integer}, \quad n = 1, 2, \dots, N \\
 & i_n \text{ integer}, \quad n = 1, 2, \dots, N.
 \end{aligned}$$

A well-known monotonicity result on convex production planning problems [51] provides that an optimal response to a unit increase in one of the demands is to increase optimal production by one unit. More formally,

Lemma 1 [51]. *Suppose $x_1^*, x_2^*, \dots, x_N^*$ is an optimal production schedule for demands $d_1, d_2, \dots, d_N$. If one of these demands is increased by one unit, it is optimal to increase one of these production levels by one unit.*

A special case of this monotonicity result that is presented in Ref. 4 was employed in Ref. 27 to first prove monotonicity of optimal production levels in horizon length and then establish the existence of forecast horizons for class Φ . Specifically, they embedded an N horizon problem $(P^{\phi N})$ in an $N+1$ horizon problem by setting demand in the $N+1$ st period to zero. Because it is optimal to end period N with zero inventory in the N horizon problem, an optimal production schedule for $(P^{\phi N})$, when appended with zero production in period $N+1$, results in an optimal production schedule for the embedded $N+1$ horizon problem. Then, if we increase the demand in the $N+1$ st period to its actual value d_{N+1}^ϕ , one unit at a time, it is optimal to increase production levels unit by unit. This leads to the conclusion that *increasing the problem horizon does not decrease optimal production levels*.

The idea of vanishing tail costs in discounted problems and the fact that optimal production levels remain bounded (owing to

strictly positive marginal production costs) were then used in Ref. 27 to prove value convergence of finite horizon truncations: optimal finite horizon costs denoted $C^*(\phi_N)$ converge to the optimal infinite horizon cost denoted $C^*(\phi)$ as $N \rightarrow \infty$. Finite horizon optimal production levels $x_n^*(\phi_N)$ incrementally constructed using the above procedure then converge monotonically upward to an infinite horizon optimal production level $x_n^*(\phi)$ for every period n as $N \rightarrow \infty$ *without requiring uniqueness of infinite horizon optimal production schedules*. In fact, because production levels are integers, convergence implies that for some horizon $N^*(\phi)$ that is long enough,

$$x_1^*(\phi_N) = x_1^*(\phi) \text{ for all } N \geq N^*(\phi). \quad (1)$$

Thus $N^*(\phi)$ is a solution horizon for ϕ (see Ref. 27 for proofs and other details).

It is even more interesting that monotonicity leads to *closed form formulas* for forecast horizons. For instance, note in the above production planning situation that when the horizon increases from N to $N+1$, optimal first period production either increases or remains the same. If the first period production *must* increase, then the horizon cannot be longer than a certain length. To see this, observe that if the first period production increases as a result of an increase in horizon length, this extra production in the first period must be carried all the way to period $N+1$ (because optimal production levels in intermediate periods are nondecreasing in horizon). This implies that carrying inventory forward from the first period to the $N+1$ st period must be cheaper than producing in the $N+1$ st period. In particular, the least expensive way of producing in the first period and carrying inventory forward to period $N+1$ must be cheaper than the most expensive way of producing in period $N+1$. This leads to the following inequality:

$$c + h \frac{1 - \alpha^N}{1 - \alpha} \leq \gamma \alpha^N. \quad (2)$$

In other words, if optimal first period production must increase as a result of the increase

in horizon length from N to $N+1$, then N cannot be more than N^* given by [see formula (29) in Ref. 27]

$$N^* = \left\lceil \frac{(1 - \alpha)c + h}{(1 - \alpha)\gamma + h} \right\rceil, \quad (3)$$

where $\lceil y \rceil$ denotes the smallest integer strictly greater than y . Intuitively, N^* is the longest number of periods over which it may be optimal to carry inventory forward; the first period decisions are thus decoupled from periods beyond N^* . Most importantly, this closed form formula does not depend on any specific data parameter values but rather only on properties of class Φ . That is, N^* in Equation (3) is a forecast horizon for class Φ . More strongly, it was proven in Ref. 21 that this N^* is the minimum forecast horizon for class Φ , that is, it is not possible to provide a shorter forecast horizon without explicitly knowing specific data parameter values. Numerical illustrations in Ref. 27 demonstrate that N^* is often very short, that is, a few days or a few weeks.

The above device of embedding an N horizon problem in an $N+1$ horizon problem and appealing to optimal production level monotonicity in demand to establish optimal production level monotonicity in horizon length may not always work. For example, it fails when backlogging is allowed. This is because even though it may be optimal to end the N horizon problem with zero inventory, it may no longer be optimal to end the N th period of the embedded $N+1$ horizon problem with zero inventory. In particular, it may be optimal to carry negative inventory, that is, to backorder in the N th period of the embedded problem. Analysis similar to the one presented above however was successfully carried out in Ref. 21 for the backlogging case by embedding the N horizon problem in an infinite horizon problem with zero demand in periods $N+1$ and beyond. This was possible because the embedded infinite horizon problem reduces to an $N+M$ horizon problem with zero terminal inventory, where M is an upper bound on the number of successive periods in which inventory may be optimally backordered. Lemma

0 then extends to this $N + M$ horizon problem with backlogging leading to a closed-form forecast horizon formula.

SOME NEW RESULTS AND FUTURE DIRECTIONS

The idea of exploiting policy monotonicity has also been extended to stochastic problems. For example, a closed form formula for a forecast horizon in production planning problems with stochastic demands and linear costs was provided in Ref. 20. A general theory for employing policy monotonicity to algorithmically discover forecast horizons in a class of nonhomogeneous infinite horizon MDPs is presented in Ref. 40. The results in Ref. 40 use classic work on establishing monotone optimal policies in MDPs through supermodular functions [52]. There does not seem to be too much work, however, on identifying diverse applications where the first period decision is monotone in horizon length, and this may be a fruitful direction for research in the near future. The close connection between Bellman's equations for *stationary* MDPs and finite-dimensional linear programs has recently proven quite helpful in approximate solution of large-scale stationary MDPs earlier considered intractable [53]. Unfortunately, the linear programs that arise from *nonstationary* MDPs have a countably infinite number of variables and a countably infinite number of constraints, and hence present several mathematical difficulties [54–56]. However, there has been some recent progress in better understanding algebraic and geometric properties of such infinite-dimensional linear programs [57–63]. These results may provide an interesting foundation for further exploring nonstationary infinite horizon optimization problems.

INFINITE LINEAR PROGRAMS

THOMAS C. SHARKEY
Department of Decision Sciences
and Engineering Systems,
Rensselaer Polytechnic Institute,
Troy, New York

Many important optimization problems that can be formulated as linear programs involve decision making or planning over time. If the horizon of the problem is finite and we are concerned with making decisions at discrete points in time, we obtain a classic finite-dimensional linear program. However, in many cases, there is no natural horizon or we are interested in making decisions for every point in time in a continuous setting. We then obtain a linear program in an infinite-dimensional space or, equivalently, an infinite linear program. Infinite linear programs have many applications in solving classic optimization problems over an infinite horizon including deterministic or stochastic dynamic programs with countable states [1], production planning problems [2–4], equipment replacement problems [5,6], capacity expansion problems [5,7], problems involving exploiting resources [8], and network flow problems [4,9].

The analysis of infinite linear programs and the development of solution methods for them is quite difficult due to the fact that many of the fundamental properties of finite-dimensional linear programming fall apart in an infinite-dimensional space. It is not straightforward to characterize an extreme point of the feasible region of an infinite linear program through a decomposition of basic and nonbasic variables [4,10], which is a building block of the simplex method for linear programs. In fact, an infinite linear program may not even have an extreme point even when all variables are bounded [11]. Weak duality does not hold using the natural dual of an infinite linear program [2], which is analogous to the familiar finite-dimensional linear programming dual problem. Weak

duality may not hold even when the infinite linear program has a single feasible solution [9]. This obstacle can be overcome in a relatively straightforward manner by posing the infinite linear program and its dual in the appropriate infinite-dimensional spaces. However, these spaces are often too restrictive to obtain strong duality results [11,12]. Another complication in extending the simplex method to infinite linear programs is that there can exist an infinite sequence of adjacent extreme points with strictly decreasing objective functions (in a minimization problem) that do not converge to the optimal objective function value [1].

The focus of this article is on infinite linear programs where both the number of variables and the number of constraints are infinite. For an introduction to infinite linear programs where either the number of variables or the number of constraints is finite, that is, semi-infinite linear programs, we refer the interested reader to Ref. 13 or Ref. 14. The remainder of this article is split into two sections on different classes of infinite linear programs. In the section titled “Countable Infinite Linear Programs”, we discuss infinite linear programs where the number of variables and the number of constraints are countable, and, in the section titled “Continuous Linear Programs”, we discuss infinite linear programs where the number of variables and the number of constraints are uncountable, that is, the class of so-called continuous linear programs (CLPs).

COUNTABLE INFINITE LINEAR PROGRAMS

A countable infinite linear program (CILP) is a linear program that has a countably infinite number of variables and constraints. CILPs arise in many of the motivating applications of infinite linear programs such as infinite-horizon deterministic and stochastic dynamic programs with countable states and infinite-horizon production planning problems. More generally, sequential

decision-making problems over time in which the decision points are discrete and there does not exist a natural finite planning horizon can often be formulated as CILPs. The mathematical formulation of a CILP in standard form (1,10) is given by

$$\text{minimize } \sum_{j=1}^{\infty} c_j x_j$$

subject to

$$\begin{aligned} \sum_{j=1}^{\infty} a_{ij} x_j &= b_i \quad \text{for } i = 1, 2, \dots \\ x_j &\geq 0 \quad \text{for } j = 1, 2, \dots \end{aligned} \quad (1)$$

The standard form of a CILP is analogous to the standard form of a traditional finite-dimensional linear program; however, it begins to highlight the difficulties in analyzing infinite linear programs. For example, the infinite sums involved in the CILP may not be well defined (if $x_j = 1$ for all $j = 1, 2, \dots$ is feasible and $c_j = (-1)^j$ for $j = 1, 2, \dots$ then the objective function will not be well defined for this solution). There are many common assumptions placed on CILPs including (i) assuming directly that the infinite sums are well defined, (ii) each constraint contains a finite number of variables (which implies that the constraints are well defined), (iii) there exists nonnegative numbers u_j for $j = 1, \dots$ such that for every feasible solution to the CILP that $x_j \leq u_j$ for $j = 1, 2, \dots$ and $\sum_{j=1}^{\infty} |c_j| u_j < \infty$ (implying that the feasible region is compact and the objective function is well defined and continuous). These assumptions are often naturally satisfied by the motivating applications of CILPs since, typically, we are making a finite set of decisions from a finite set of alternatives at each decision epoch in which the costs of the decisions will be discounted over an infinite horizon. There are many obstacles in the analysis of CILPs and the development of solution methods (e.g., a simplex method) for them. In this section, we will review these obstacles and the methods that have been used to overcome them. We will first discuss an example of a class of CILPs, network flow

problems with a countably infinite number of nodes and arcs [4,9].

In particular, we consider an infinite directed network, $G = (N, A)$, where $N = 1, 2, \dots$ is the set of nodes and $A \subset N \times N$ is the set of arcs. We will let $x \in \mathbb{R}^{|A|}$ denote a vector of flows in this infinite network. The regularity assumption that each node has a finite in- and out degree ensures that the set A is countable. Our infinite-dimensional minimum cost network flow problem can be formulated as

$$\text{minimize } \sum_{(i,j) \in A} c_{ij} x_{ij}$$

subject to

$$\begin{aligned} \sum_{j:(j,i) \in A} x_{ji} - \sum_{j:(i,j) \in A} x_{ij} &= b_i \quad \text{for } i = 1, 2, \dots \\ x_{ij} &\leq u_{ij} \quad \text{for } (i,j) \in A \\ x_{ij} &\geq 0 \quad \text{for } (i,j) \in A, \end{aligned} \quad (2)$$

where $c \in \mathbb{R}^{|A|}$ is a vector of costs, $u \in \mathbb{R}_+^{|A|}$ is a vector of nonnegative upper bounds, and $b \in \mathbb{R}^{|N|}$ is a vector of supplies. This formulation is analogous to the finite-dimensional minimum cost network flow problem [15] and ensures that a sufficient amount of flow leaves supply nodes (those nodes i such that $b_i < 0$) and is delivered to demand nodes (those nodes i such that $b_i > 0$) while respecting the flow bounds on the arcs. This problem can be easily converted to the standard form of a CILP by adding slack variables to the flow-bound constraints. Many of the obstacles that arise in the analysis of CILPs also arise in the analysis of these infinite-dimensional network flow problems.

Finite-Dimensional Truncations

One of the main goals in the study of CILPs is to develop solution methods for them. In order for a solution method to be viable in a real-world application, it needs to provide solutions in a finite amount of time. However, it is clear that we need an infinite amount of information (e.g., the cost parameters of the variables, the coefficients associated with each variable in each constraint, and the constants associated with each constraint)

to even characterize a CILP. Therefore, a fundamental issue in the study of CILPs is to develop methods that perform a finite amount of work using a finite amount of information and provide (partial) solutions to the CILP. Many methods that examine finite-dimensional truncations of the problem for various special classes of CILPs have been developed. These finite-dimensional truncations typically consider the first n variables and the constraints that contain only the first n variables, although we may not consider a truncation for every possible value of n . For many of the motivating applications of CILPs, the truncations are readily available by considering each decision epoch as a truncation. Moreover, any CILP in which each constraint contains only a finite number of variables with nonzero coefficients has a natural set of truncations [1,2]. There has been much attention devoted to examining various classes of infinite-horizon optimization problems through a series of truncations to establish *planning* or *forecast* horizons [6,16–26]. These planning or forecast horizons are finite-dimensional truncations that have the desirable property that the first decision (for sequential decision-making problems) is optimal or near-optimal to the infinite-horizon problem. From a theoretical standpoint, the analysis of finite-dimensional truncations of CILPs is used in developing duality theory for CILPs [2,3] and guaranteeing infinite-dimensional simplex methods converge to the optimal solution value of the CILP [1,9].

Extreme Points of the Feasible Region

The study of the extreme points of CILPs is important since we know that the optimum of a CILP occurs at an extreme point [27] and extensions of the simplex method to infinite-dimensional spaces would traverse the extreme points of the feasible region. It is shown in Ref. 28 that the extreme points of finite-dimensional projections of a CILP converge in the product topology to the set of extreme points of the CILP. The finite-dimensional projection of a CILP onto the space $\mathbb{R}^n$ contains a particular n -dimensional vector if and only if the vector corresponds to the values of the first n variables for some feasible solution of the

CILP. More precisely, the projection of an infinite-dimensional set $S \in \mathbb{R}^\infty$ (e.g., the constraint set of a CILP) onto the space $\mathbb{R}^n$ is defined as $S_n = \{p_n(x) : x \in S\}$ where $p_n(x)$ is the first n entries of the infinite-dimensional vector x . The relationship between the projections of a CILP and appropriately defined truncations of CILPs is important in the development of a Shadow Simplex method for CILPs in Ref. 1.

The characterization of an extreme point of a CILP cannot typically be done through a decomposition of basic and nonbasic variables. As an example, recall that for a finite network flow problem, a solution x is an extreme point if and only if the graph containing all “free” arcs, that is, (i, j) such that x_{ij} is strictly between its bounds, does not contain a cycle [15]. For infinite network flow problems with a countably infinite number of nodes and arcs, if x is an extreme point, then the free arc graph does not contain a cycle but the converse is not necessarily true [4]. Example 1 discusses a problem that illustrates this issue.

Example 1. Consider the infinite network flow problem in Fig. 1 (which is modified from an example in Ref. 4) where node 1 is a supply node that must ship one unit of demand (i.e., $b_1 = -1$) from it and all other nodes $i = 2, 3, \dots$ are transshipment nodes (i.e., $b_i = 0$). The flow bound on each arc is 1. The only two extreme points of this problem are the solution that sends the unit of flow along the “upper” path (nodes $1 - 2 - 4 - \dots$) and the solution that sends the unit of flow along the “lower” path (nodes $1 - 3 - 5 - \dots$). Any solution where the unit of the flow is split between these two paths is not an

Figure 1. An example problem where an acyclic free arc graph does not imply an extreme point.

extreme point; however, the free arc graph of the solution will be acyclic.

The work in Ref. 4 provides necessary and sufficient conditions for a solution of an infinite network flow problem to be an extreme point of the feasible region. The main issue that limits Ref. 4 from characterizing an extreme point through a decomposition of basic and nonbasic variables is that the support of the free arcs may go to zero, that is, there can exist an edge (i, j) such that x_{ij} is arbitrarily close to its lower or upper bound. The *nonvanishing support* condition developed in Ref. 4 guarantees that an extreme point can be characterized through a decomposition of basic and nonbasic variables. This condition is met by all extreme points of problems with integral capacities and demand. Therefore, all extreme points of problems with integral capacities and demand can be characterized through a decomposition of basic and nonbasic variables. The motivating applications of infinite network flow problems typically have integral capacities and demand, so this condition is not necessarily restrictive. It is shown in Ref. 10 that the nonvanishing support condition guarantees that an extreme point can be decomposed into basic and nonbasic variables for general CILPs.

Duality Theory for Countable Infinite Linear Programs

Duality theory is of critical importance in the study of linear programs. The dual problem provides lower bounds (or upper bounds) on the objective function value of the primal problem and the dual variables have important economic interpretations as the shadow prices of the constraints. There are many examples of duality failing to hold for CILPs [9,11,29] when using the “natural” dual [2] of the CILP, which is analogous to the dual linear program in finite-dimensional linear programming. In fact, weak duality fails to hold even for the simple infinite network flow problem discussed in Example 1.

Example 1 Revisited. (This example is modified from an example in Ref. 9.) The

mathematical formulation of this problem is given by

$$\text{minimize } c_{12}x_{12} + \sum_{i=3}^{\infty} c_{i-2,i} x_{i-2,i}$$

subject to

$$\begin{aligned} -x_{12} - x_{13} &= -1 \\ x_{12} - x_{24} &= 0 \\ x_{i-2,i} - x_{i,i+2} &= 0 \quad \text{for } i = 3, 4, \dots \\ 0 &\leq x_{12} \leq 1 \\ 0 &\leq x_{i-2,i} \leq 1 \quad \text{for } i = 3, 4, \dots \end{aligned} \quad (3)$$

The natural dual of this problem, which is analogous to the dual of a finite-dimensional network flow problem [15], is given as

$$\text{maximize } -\pi_1 - \theta_{12} - \sum_{i=3}^{\infty} \theta_{i-2,i}$$

subject to

$$\begin{aligned} \pi_2 - \pi_1 - \theta_{12} &\leq c_{12} \\ \pi_i - \pi_{i-2} - \theta_{i-2,i} &\leq c_{i-2,i} \quad \text{for } i = 3, 4, \dots \\ \theta_{12} &\geq 0 \\ \theta_{i-2,i} &\geq 0 \quad \text{for } i = 3, 4, \dots \end{aligned} \quad (4)$$

where π_i is the dual multiplier associated with the flow-balance constraint of the i th node and θ_{ij} is the dual multiplier associated with the flow-bound constraint of arc (i, j) . For Problem 3) when all arc costs are zero, the optimal solution to it will have cost 0. Any solution of the form $\pi_i = \Pi$ for $i = 1, 2, \dots$, $\theta_{12} = 0$, and $\theta_{i-2,i} = 0$ for $i = 3, 4, \dots$ will be feasible to the dual problem (Eq. 4). Therefore, for solutions of this form where $\Pi < 0$, the objective function value of the dual solution exceeds the optimal objective function solution of the primal problem and thus weak duality fails to hold.

Weak duality can be obtained somewhat easily by posing the CILP and its dual in appropriate infinite-dimensional spaces, but these spaces are often too restrictive to guarantee strong duality. Therefore, the

establishment of a dual problem for CILPs that obtains both weak and strong duality remains a challenging problem. The ideal approaches to obtain this dual problem would employ, to the greatest extent possible, the deep understanding that we have of the dual problem in finite-dimensional linear programming.

The vast majority of the work in duality theory for CILPs focuses on the case where each constraint has a finite number of variables. Strong duality results are obtained for a general class of CILPs in Ref. 30 under a set of assumptions relating to degeneracy; however, these assumptions are quite restrictive in the infinite-dimensional setting. The work in Refs 16, 17, 31, and 32 provides duality results for special classes of CILPs. These works along with Refs 2 and 3 develop the duality results indirectly through the inheritance of properties from finite-dimensional truncations of the CILP. Weak and strong duality results are obtained for CILPs with inequality constraints in Refs 2 and 3 under a particular restriction on the constraint matrix. This restriction requires that “past” decisions in “future” constraints eventually have only nonnegative coefficients. For example, in production planning problems, this restriction is naturally satisfied since the inventory coming into a time period is the “past” decision and the production/inventory-balance constraint of the time period is the “future” constraint. However, this restriction does not allow the results of Refs 2 and 3 to be applied to equality-constrained CILPs. The *transversality* condition is introduced in Ref. 2 to obtain strong duality results. This condition requires that the dual variable (or multiplier) associated with the i th constraint goes to zero as i goes to infinity. The transversality condition is used in Ref. 9 to develop weak and strong duality results for infinite network flow problems with equality constraints. Duality theory for a general class of CILPs with equality constraints is developed in Ref. 33.

Infinite-Dimensional Simplex Methods

There has been success in extending the simplex method for linear programming to CILPs. The network simplex method

was extended to solve problems in infinite networks in Ref. 9. This was a true infinite-dimensional network simplex method, that is, it moved between adjacent extreme points of the feasible region of the problem using the characterization of extreme points from Ref. 4. However, in general, each pivot operation could require an infinite amount of work. For the class of infinite network flow problems whose flow-balance constraints are inequalities (i.e., we do not need to ship all supply from a node and we can leave more at a node than its demand), which include production planning problems, it is shown that each pivot operation can be performed in a finite amount of time.

A shadow simplex method for CILPs is developed in Ref. 1. The term *shadow* comes from the fact that the method performs computations (in particular, pivot operations from the simplex method for finite-dimensional linear programming) on the projections, that is, the shadows, of the feasible region of the CILP into finite-dimensional spaces. It is assumed that appropriately defined finite-dimensional truncations of the CILP are equivalent to the projections of the infinite-dimensional feasible region. This assumption guarantees that an extreme point of the finite-dimensional truncation can be extended to an extreme point for all truncations that are in a larger-dimensional space (including the infinite-dimensional space) using the results of Ref. 28. Although this assumption appears restrictive, it is shown in Ref. 1 that we can make this assumption without loss of generality for infinite-horizon deterministic or stochastic dynamic programs using a “Big-M” method and for production planning problems with a feasible solution using a “valid inequality” approach. This Shadow Simplex method solves projections of increasing dimension using the traditional simplex method. It does not, however, correspond to a true infinite-dimensional simplex method in all situations since the move from the optimal solution to a particular finite-dimensional projection to the initial solution of the next projection in higher dimensional space does not need to be between two adjacent extreme points. However, for the important cases of

infinite-horizon deterministic and stochastic dynamic programs, it is shown that the method does indeed correspond to a true infinite-dimensional simplex method.

CONTINUOUS LINEAR PROGRAMS

CLPs are infinite linear programs where the infinite dimension arises from the fact that we need to make decisions at every point in time in a continuous setting. The formulation of a CLP is given by

$$\begin{aligned} & \text{maximize } \int_0^T c(t)^\top x(t) dt \\ & \text{subject to} \\ & B(t)x(t) + \int_0^t K(s,t)x(s) ds \leq b(t) \\ & \quad \text{for all } t \in [0, T] \\ & x(t) \geq 0 \quad \text{for all } t \in [0, T]. \end{aligned} \quad (5)$$

This problem was discussed in Refs 34 and 35 to model some economic processes. It is clear that CLPs have an uncountable number of decision variables and an uncountable number of constraints since we are considering all points in time over a continuous and finite horizon. The obstacles of linear programming in infinite-dimensional spaces have been overcome to some degree for CLPs and various special cases of them. Typically, these special cases of CLPs come in the form of restricting the functional spaces associated with the parameters in the problem and the functional space of the solutions. Extreme points of CLPs have been characterized for various forms of functional spaces of the parameters in Ref. 36. There have been duality results for CLPs [37] and interior point methods have been analyzed to solve them [38]. For a complete overview of the theory developed for CLPs, we refer the reader to Ref. 11.

As an example of a CLP, we will consider the problem of maximizing the total flow sent from a source node to a sink node over a finite horizon in a continuous-time setting [39,40]. In particular, we consider a directed network,

$G = (N, A)$, where we are interested in sending the flow from the source node u to the sink node v over the horizon $[0, T]$. Each intermediate node $i \in N \setminus \{u, v\}$ has an associated function a_i that represents its storage capacity as a function of time and each arc $(i, j) \in A$ has an associated function u_{ij} that represents its flow bound as a function of time. We then seek a collection of nonnegative functions x_{ij} over $[0, T]$ where $x_{ij}(t)$ represents the amount of flow on arc (i, j) at time $t \in [0, T]$ that maximizes the flow from the source to the sink. The mathematical formulation of this problem is as follows:

$$\begin{aligned} & \text{maximize } \int_0^T \left(\sum_{i:(i,v) \in A} x_{iv}(t) - \sum_{i:(v,i) \in A} x_{vi}(t) \right) dt \\ & \text{subject to} \\ & \int_0^t \sum_{j:(j,i) \in A} x_{ji}(t) dt - \int_0^t \sum_{j:(i,j) \in A} x_{ij}(t) dt \leq a_i(t) \\ & \quad \text{for } i \in N \setminus \{u, v\}, t \in [0, T] \\ & x_{ij}(t) \leq u_{ij}(t) \text{ for } (i, j) \in A, t \in [0, T] \\ & x_{ij}(t) \geq 0 \text{ for } (i, j) \in A, t \in [0, T]. \end{aligned} \quad (6)$$

The objective function of this problem maximizes a function that represents the total amount of flow that is absorbed by the sink node v over the horizon of the problem. The first set of constraints in this formulation is a generalization of the flow-balance constraints. The first integral in these constraints represents the total amount of flow that has arrived at the node i in the interval $[0, t]$ while the second integral represents the total amount of flow that has left the node i in the interval $[0, t]$. Therefore, these constraints guarantee that the amount of flow left the node i at any point in time t does not exceed the storage capacity of the node at that time.

Separated Continuous Linear Programs

An important subclass of CLPs is the so-called separated continuous linear programs (SCLPs) where the integral constraints and the instantaneous constraints are separated.

In other words, the formulation of a SCLP is given by

$$\text{maximize } \int_0^T c(t)^\top x(t) dt$$

subject to

$$\begin{aligned} \int_0^t Gx(s) ds + y(t) &= a(t) \text{ for all } t \in [0, T] \\ Hx(t) + z(t) &= b(t) \text{ for all } t \in [0, T] \\ x(t) &\geq 0 \text{ for all } t \in [0, T]. \end{aligned} \quad (7)$$

SCLPs have applications in job-shop scheduling [41] and continuous-time network flow problems [39,40,42]. The extreme points of SCLPs were characterized in Ref. 43 in a manner that is analogous to the basic solutions of finite-dimensional linear programming problems. The work in Ref. 44 provides characterizations on the structure of the optimal solutions to SCLPs (such as piecewise constant or piecewise analytic) based on various assumptions on the problem data.

Clearly, we can discretize both a CLP and an SCLP in order to end up with a finite-dimensional linear program. This is similar to approximating the CLPs through a finite-dimensional truncation. It turns out that the discretization of SCLPs proves quite powerful in analyzing them. The work in Ref. 45 developed an algorithm for classes of SCLPs under the assumptions that $a(t)$ is piecewise linear and continuous, $b(t)$ is piecewise constant, and the functions $c(t)$ are piecewise linear. This work develops an improvement step for any feasible, nonoptimal solution to the SCLP, which relies on examining an appropriate discretization of the problem. This improvement step is used to develop an algorithm to solve the SCLP and to prove a strong duality result. The convergence of this algorithm was not proven until the work in Ref. 46. However, the ideas behind the algorithm (especially the discretization) were used in developing duality theory for SCLPs in Ref. 47. This algorithm has been extended to the case where the cost functions $c(t)$ are piecewise analytic in Ref. 48.

An algorithm based on the simplex method was developed in Ref. 49 for SCLPs under the

assumptions that $a(t)$ is linear, the functions $c(t)$ are linear, and $b(t)$ is constant. The algorithm in Ref. 49 solves these SCLPs directly, that is, without discretizing the problem. A limitation of the algorithm is that its pivot operations are well defined only under a nondegeneracy assumption (although any problem can be perturbed to a nondegenerate problem). However, simple conditions for a problem to be nondegenerate are provided. In Ref. 49, an appropriate dual problem is defined, a pivotlike operation is developed to move from extreme point to extreme point, and a proof that the algorithm solves the problem by pivoting to a *finite number* of extreme points is provided.

Continuous-Time Network Flow Problems

There has been much work done for the special class of CLPs with an underlying network structure. In other words, we are given a network and we need to determine the amount of flow on each arc as a function of time (i.e., the value $x_{ij}(t)$ corresponds to the amount of flow on edge (i, j) at time t) so that each node satisfies a generalization of the flow-balance constraints at each point in time [39]. These continuous-time network flow problems have various objectives including maximizing the amount of flow from a source to a sink over a finite horizon [39], minimizing the amount of time needed to empty the network of excess supply [50], and minimizing the total cost incurred by meeting specified demands over the horizon (which is the extension of the minimum cost flow problem to the continuous setting, see Ref. 42). The work in Ref. 39 extends the classic max-flow min-cut result to continuous maximum flow problems where the edges have zero traversal time. This result is generalized to the case where edges have traversal times in Ref. 40. The network simplex algorithm was extended to separated continuous network flow problems in Ref. 42; however, this method is known not to converge to the optimal solution of the problem. A solution method that specializes the algorithm of Ref. 45 to separated continuous network flow problems was developed in Ref. 51 and shown to converge to the optimal solution.

Another stream of research related to continuous-time network flow problems is to develop efficient (i.e., polynomial-time) algorithms or approximation algorithms for their special classes. The work in Ref. 52 extends various polynomial-time algorithms for dynamic network flow problems in a discrete time setting to a continuous time setting under the assumptions that edge-capacities and traversal times are integral and constant over time. Approximation schemes for various continuous-time network flow problems are given in Refs 53 and 54. The assumptions placed on the data in Ref. 53 guarantee that the optimal solution to the problem is piecewise constant using the work of Ref. 43. However, it is not known if the number of pieces of the optimal solution is polynomial in the input size of the problem. This problem is overcome (to a certain extent) in Ref. 53 by developing an algorithm that returns a solution whose value is arbitrarily close to the optimal objective function value and whose size (i.e., the number of pieces characterizing it) is polynomial in terms of the input into the algorithm. This solution is obtained by solving a discretized version of the continuous problem.

SUMMARY

We have discussed the many challenges that arise in the study of infinite linear programs. Many of these challenges come from the fact that the fundamental properties of finite-dimensional linear programming (e.g., the characterization of extreme points or duality theory) do not apply or extend in a straightforward manner to infinite linear programs. We discussed the two main classes of infinite linear programs, CILPs and CLPs. For CILPs, we saw that the analysis of finite-dimensional truncations of the infinite linear program were used to overcome many of the challenges faced by this class of infinite linear programs. Similarly, finite-dimensional discretizations of CLPs are important in their analysis. These methods use our vast knowledge of finite-dimensional linear programming to aid in the analysis of infinite linear programs.

There has been success in developing simplex (or simplex-like) methods to solve infinite linear programs that can perform operations in finite time with finite information. The development of simplex (or simplex-like) methods for new classes of infinite linear programs is an important area of future research, especially those methods that reduce to “true” simplex methods, that is, ones that move between adjacent extreme points.

INTRODUCTION

Information sharing is crucial for supply chain coordination, as no supply chain can run smoothly without information. In this article, we first provide an anatomical view of the different types of information that exist in a supply chain. Then, we delve into each by reviewing relevant literature. The goal of this article is to provide a comprehensive but *nontechnical* introduction to the literature. For a technical treatment of this topic, readers are referred to Chen [1].

The literature on information sharing in supply chains is vast. While an exhaustive review is not possible here, we try to highlight those that make recent contribution to the literature, especially those appearing in the last 15 years (1994–2009). Whenever possible we juxtapose empirical research along with analytical papers on a given topic so as to highlight its relevance to practice. This article also intersects with a number of other articles in this book, such as those on supply chain coordination, (see *Supply Chain Coordination*), inventory record accuracy (see *Inventory Record Inaccuracy in Retail Supply Chains*), vendor managed inventory (see *Vendor-Managed Inventory*) and RFID applications (See *Inventory Inaccuracies in Supply Chains: How Can RFID Improve the Performance?*). Readers are referred to those articles for discussion on specific topics.

RESEARCH OVERVIEW

In this section, we first provide an overview of different types of information, then we enumerate the major research themes associated with information in supply chains.

Different Types of Information in a Supply Chain

Let us start by looking at a simple three-stage serial supply chain for a product depicted below (Fig. 1).

In this typical supply chain, demand arrives at the retailer, who orders from its distribution channel, who in turn orders from the manufacturer. As one of the supply chain parties, what information is needed in order for it to optimize its operations? Let us enumerate the types of information that are explicit or implicit in the supply chain:

- *Demand / Orders.* Supply chains exist in order to match demand with supply, therefore demand or order information is perhaps the most commonly shared type of information in a supply chain.
- *Forecasts.* Sometimes what are received from the downstream party or sent to its upstream party are not orders per se, but just forecasts; that is, intention to buy with no commitment, either in the form of a point estimate or a distribution.
- *Inventory / Order Status Information.* This includes order status information such as the location and quantity of inventory at each stage in the system. It may also include what inventory policies are being used at each stage of the system.
- *Lead Time information.* It includes order lead time and demand lead time (whose exact definition will be dealt with later).
- *Costs.* These may include the cost of manufacturing, distributing, or selling

Figure 1. A Simple three-stage serial supply chain

products. Such information is not always available to all supply chain parties.

There are several other less-researched categories of information. For example, product development information of manufacturers. (Does it offer any benefit if a manufacturer shares its product development information with its downstream parties?) Other examples include information on supply chain structures, capacity, and types of contracts. We will discuss them in the latter sections of this article.

Most of the research in information sharing assumes that information existing in the supply chain is accurate (except for those dealing with strategic information-sharing behavior). However, that is frequently not true in practice. Supply chain parties have to deal with inaccurate information. What if we know some information is subject to errors, and may be inaccurate? Is it beneficial to have the knowledge that some information is bad? We will cover literature dealing with such questions as well. Next, we briefly summarize major research themes in the literature that are related to information sharing in supply chains.

Research Themes

Research related to information and information sharing in the OR/OM (operations management) field has been evolving around, but is not limited to, the following research questions:

1. What is the value of having a certain type of information in a supply chain, such as demand forecast or order information? Or, put in another way, what is the impact of *not* having a certain type of information?
2. How can information be used in improving system efficiency? What are the

mechanisms through which information would create value in improving the efficiency of supply chain parties?

3. What are the incentive issues in information sharing?
4. How is the value of information affected by contracts, organizational factors of supply chain parties, and market structure?

With these questions in mind, we review relevant literature by each category of information. Within each category, we organize articles by their research topics and contribution to the literature.

LITERATURE

Demand-Related Information

Demand or its related information may be on the top of the list if one talks about information sharing in a supply chain. There has been intense interest during the past decade on studying the value of sharing such demand information in various types of inventory systems. As a result, a significant body of knowledge has been created in this area.

Value of Demand Information. Chen [2] has contributed to one of the earliest works that study the value of demand information in an N -stage serial inventory system. In its model, each stage uses a stage-specific recorder point/order quantity, namely (R, nQ) policy. That is, whenever the inventory position at a stage falls below R , order nQ units to bring its inventory position back to be above R . Here n is the minimum integer required to achieve that. The paper quantifies the value of demand information by comparing two types of (R, nQ) policy. The first is based on echelon-stock calculation, which is the inventory position of the subsystem, which includes the stage itself and all

the downstream stages. This policy, therefore uses centralized demand information of all stages. The other policy is based on installation stock, which is its local inventory position. The difference of cost between the two policies is the value of having centralized information. Results show that such a value ranges from 0 to 9%.

Gavirneni *et al.* [3] studied a two-stage capacitated inventory system with a supplier and a retailer, where the retailer uses an (s, S) policy. Value of information is studied in a progressive fashion with three scenarios. The base scenario is where the only information the supplier observes is the retailer's orders, which is assumed to be i.i.d. In the second scenario, the supplier knows the following information: demand distribution of the retailer, that the retailer uses an (s, S) policy and its specifics, and when the last order from the retailer occurred. In the third scenario, the supplier has full information. It is shown that from the base scenario to the second, the supplier's cost decreases from 10 to 90%, whereas the cost decrease from the second to the third ranges from 1 to 5%.

Lee *et al.* [4] study a two-stage serial supply chain with nonstationary demand. In particular, end-product demand is assumed to follow an AR(1)(Autoregressive) process. The key question here is how large the benefit is for the supplier to observe the end-product demand, instead of just the retailer's orders. They show that the benefit of sharing demand information can be quite large, especially when demand correlation is high. Gaur *et al.* [5] study a model with autoregressive moving average (ARMA) demand, and find that the value of sharing demand information (or inferring demand information from orders) can be significant.

Aviv and Federgruen [6] study the value of demand information in the context of the Vendor Managed Inventory (VMI) program. In their model setup, there is one supplier who replenishes for multiple independent retailers. The value of information is obtained by comparing the supply chain costs in a decentralized model with no information sharing (Model 1) against that with a decentralized one with information sharing (Model 2), and finally a supplier-controlled

system with full information, that is VMI. The authors find that the average savings in cost from Model 1 to Model 2 is about 2%, and that from Model 2 to Model 3 is about 4.7%. Article 4.5.3.4 discusses in further detail the benefits (and challenges) in VMI.

It should be noted that not all inventory models lead to the conclusion that there is significant benefit from sharing demand information. Raghunathan [7] studies the supply chain setting presented in Lee *et al.* [4], and shows that if the manufacturer can improve its forecasting method by using the retailer's entire order history, the benefit of sharing demand information may not be necessarily large. Another example is given in the study by Graves [8], where a two-stage serial system with autoregressive integrated moving average (ARIMA) $(0, 1, 1)$ demand was studied. He first shows that the demand process that the supplier faces is also of ARIMA $(0, 1, 1)$. In addition, there is no benefit for the supplier in observing any extra information such as the end-market demand. Chen and Lee [9] provide a unified framework that is able to resolve the differences in literature. Moreover, they show that the value of information sharing is maximized when the retailer shares its order forecasts truthfully with the supplier.

Sharing Demand Information with Competition. Recent papers have further deepened our understanding about information sharing in different supply chain settings such as among competing retailers, or among competing supply chains. Ha and Tong [10] investigate competition between two serial supply chains, each with one manufacturer and one retailer. In each supply chain, the manufacturer decides whether to invest in sharing demand size information with its respective retailer. Retailers then engage in Cournot competition based on selling quantities. The authors show that interestingly, the value of information sharing now critically depends on the contracts each supply chain adopts. With the simple linear contracts, the value of information sharing is actually negative. This is because more information allows the manufacturer to increase its profit at the

expense of the whole supply chain performance. For quantity-based contract menus, however, information sharing does bring positive value to the supply chain.

In practice, when competing customers source from the same manufacturer, information leakage has been a major concern for customers who do not intend to share their order information with their competitors [11]. Li and Zhang [12] study the implication of multiple competing retailers sharing demand information with each other, and propose a “confidentiality” scheme in information sharing. In their model, the retailers engage in Bertrand (i.e., price) competition, but they all source from one common supplier. When each of the retailers shares its information confidentially with the manufacturer, they can only infer demand information from the wholesale price that the manufacturer sets. Alternatively, retailers could choose to disclose their private information to everyone, or a selected set of all supply chain parties. Interestingly, they show that information confidentiality actually improves supply chain efficiency. This is because confidentiality alleviates the “double marginalization” problem existing when the manufacturer sets the wholesale price. Confidential information sharing vertically centralizes each retailer’s information at the manufacturer without horizontal direct disclosure to other retailers. Such strategic signaling lowers the equilibrium wholesale price and therefore improves the total supply chain profits.

Value of Advance Orders Information. Another class of demand information is advanced orders, or “pre-orders.” Sometimes, customers are willing to wait for a certain length of time before receiving and consuming a product. This advance demand information should permit suppliers to better forecast demand and replenish inventory. Tang *et al.* [13] study such benefits of having advance demand information. They consider a seasonal product with uncertain demand and long lead time (think of the production of “mooncake,” a type of pastry that is consumed for the annual “mid-autumn festival” in many Asian cultures). The

retailer can induce customers to pre-order for a discounted price before the selling season, which the authors call “Advance Book Discount” (ABD) program. The time between placement and fulfillment of these precommitted orders provides an opportunity for the retailer to update demand forecasts. The authors solve for the optimal discount rate and demonstrate the benefit of such advance demand information.

It turns out that in inventory systems there exists an elegant relationship between demand lead time, that is the time from customer’s pre-orders to their delivery dates, and supply lead time. Hariharan and Zipkin [14] formally establish the following insight: demand lead time is the opposite of supply lead times. This is intuitive in the sense that demand lead time essentially allows planners to “peek into the future” and see perfectly what orders need to be fulfilled within the demand lead time window. Therefore, while long supply lead time increases supply chain cost, obtaining such advance demand information decreases it. See also the work of Chen [15] that further generalizes such a result when customer orders are heterogeneous in their lead time. Wang and Toktay [16] study the case where demand lead time is flexible; that is, early delivery is permissible. They find that with delivery flexibility increasing, the demand lead time is more beneficial than decreasing the supply lead time.

Sharing Forecast Information

Forecast information has very different characteristics, compared to “real” information. First of all, forecasts are, by definition, imprecise. Their accuracy is dependent upon which forecasting methodologies are being used, and the forecaster’s knowledge about the underlying state of the world to be forecasted. Secondly, forecasts very often represent forecasters’ intentions, and are not contractible. Therefore, incentives in sharing forecast information become important in driving supply chain relationships. Below, we discuss each theme in detail.

How to Utilize Forecast Information in Supply Chains. Incorporating demand forecasts into production or inventory system is one of

the most fruitful areas in operations literature, and we therefore devote more space to this section.

With the increasing application of material requirement planning (MRP) system in industry, the role of forecast updating becomes even more relevant to practice. Motivated by an industry study, Heath and Jackson [17] propose a martingale model of forecast evolution (MMFE) to characterize the process of forecast evolution, and apply this model in a simulation study to analyze safety stock levels for a production and distribution system. Graves *et al.* [18] independently developed an MMFE model to study requirement planning in multistage production-inventory system. Later works that use MMFE include Güllü [19], Chen *et al.* [20], Toktay and Wein [21], and Chen and Lee [9]. Kaminsky and Swaminathan [22] consider a capacitated production planning model where forecasts are updated each period. Forecasts are modeled to become more accurate over time, as the confidence interval of forecasts in which true demand lies, decreases.

Another approach in modeling forecast updating is to assume a joint statistical distribution between two random variables (e.g., demands in two periods). Then conditional upon the realization of the first quantity, forecasts updating of the second quantity can be modeled as a conditional distribution. This approach is advantageous when those two random variables are correlated. Some of the recent examples that adopt this approach include the works of Fisher and Raman [23], Eppen and Iyer [24], Donohue [25], Gurnani and Tang [26], and Agrawal *et al.* [27].

However, Cattani and Hausman [28] question the presumption that forecasts should become more accurate over time. They show both, theoretically and empirically, that demand forecasts do not necessarily become more accurate as they are updated. They argue that such forecast churning can cause inefficiencies if the firm reacts to the wrong forecast update. Cohen *et al.* [29] and Terwiesch *et al.* [30] empirically confirm this observation, based on their study of the semiconductor equipment industry. Miyaoka and Hausman [31] show with an

inventory model using base-stock policy that “stale” forecasts do not necessarily hurt, and actually improve, supply chain benefit. See also Refs 32 and 33 on two different models on how better forecasts from downstream firms may not uniformly provide benefits for everyone in the supply chain. While some of the findings regarding the effectiveness of forecast sharing are statistical, others uncover that incentives also play an important role in determining the efficiency and effectiveness of forecast sharing. Next, we discuss related incentive issues in detail.

Incentives in Sharing Forecast Information.

Most of the work in this category is analytical. Their models set themselves apart from those inventory optimization ones in that they assume supply chain parties are strategic. That is, they seek to maximize their own profit or utility, and do not always fully cooperate in a supply chain. In the context of forecast sharing, this means that if they are the ones generating forecasts, they may not send their true forecasts; if they are at the receiving end, they may not treat received information as true, or react to it as in a centralized environment.

Lee *et al.* [34] provide one of the earliest academic discussions of problems related to order forecasts and their implication on supply chain coordination. They refer to order forecasts that are eventually cancelled as “phantom orders,” and see them as a key contributor to the bullwhip effect in supply chains. Given that for some demand outcomes the supplier may be capacity constrained, the buyer has an incentive to forecast extra orders (phantom orders), especially if scarce supplier capacity is rationed based on placed orders. Armony and Plambeck [35] investigate how such false orders can lead a manufacturer to overestimate the demand and make faulty decisions about capacity investment.

Another cause of inefficiency in the supply chain may be the misuse of statistical forecasting method. Chen *et al.* [20] show that the bullwhip effect can result if a customer uses moving average forecasting method to forecast a serially correlated demand. Watson

and Zheng [36] show that when customers overestimate the demand correlation, or use the improper forecasting tools, it can increase order volatility and in turn the bullwhip effect, and the resulting outcome can be worse than not forecasting at all.

When a supply chain party possesses private information that the other parties do not know, how to induce truth-telling in sharing forecast is an important topic. Cachon and Lariviere [37] formulate a capacity procurement game, where they distinguish between two types of buyer–supplier relations concerning forecast sharing. Under forced compliance, the supplier’s behavior is observable to the buyer. In contrast, under voluntary compliance, behavior is not verifiable and could be attributed to stochastic influences from the environment. Therefore, in order to induce the supplier to provide enough capacity for high demand, the high demand type customer has to exert extra incentive to serve as signaling device, such as fixed payment or a large firm commitment, to separate himself from a low-demand type customer. Özer and Wei [38] show that in the setting of Cachon and Lariviere [37], channel coordination is possible when combining capacity commitment contract with payback contract. Ren *et al.* [39] propose a long-term perspective of this problem. When the supply chain parties expect to transact repeatedly over a long horizon, they show that under some conditions a simple wholesale price can achieve truthful information sharing and system coordination asymptotically. See the article titled **Supply Chain Coordination** in this encyclopedia for a related discussion on supply chain coordination.

In the area of collaborative planning, forecasting, and replenishment (CPFR), Aviv [40,41] study a supply chain system where its members jointly maintain and update a single forecasting process in the system. Three types of two-stage supply chain configurations are considered. The first is where retailer and supplier coordinate inventory policy but do not share demand forecast information. In the second setting, the supplier is in charge of supply chain inventory, but retailer does not share

demand signal, while the last model is a centrally managed system with full information sharing. He shows that the benefit of sharing forecast information increases as supply chain members are able to explain a large portion of demand uncertainty through early demand information, especially in the case of correlated demand. However in this setting, firms’ incentives in forecast sharing are not considered. Deshpande *et al.* [42] propose a secure collaborative planning, forecasting, and replenishment (SCPFR) protocol that facilitates forecast sharing and inventory planning while at the same time preventing information leakage.

Inventory-Related Information

Research in this category is generally centered on studying the value of having inventory information or its related status information. The advance of information technology such as RFID has made such information, and research on this topic, increasing relevant to supply chain management practice.

Value of Inventory or Inventory Status Information. One basic question in inventory system optimization is “Is it helpful to know inventory information of downstream supply chain parties?” Researchers have studied this question with a variety of approaches: analytical modeling, controlled experiments, and empirical studies.

Cachon and Fisher [43] study this question with a one-warehouse multiretailer system. In the base case with no information sharing, both the retailers and the warehouse use an (R, nQ) policy, but the warehouse only observes the retailers’ orders. With information sharing, however, the warehouse can see retailers’ inventory status at any time. This gives the warehouse opportunities to allocate inventory optimally; this is based on the inventory need of each retailer. Using a numeric study, they show that the benefit of sharing such inventory information is 2.2% of the total supply chain cost on the average. They also study two other benefits of information technology: reducing order lead time, and reducing batch size; both improve the

physical flow of goods (as opposed to improving the information flow). It is found that the two benefits associated with improving physical flow of goods are more significant than those in sharing inventory information.

Zhang *et al.* [44] analyze a repeated game with a retailer and a supplier under asymmetric inventory information. In each period of the game, the supplier offers a contract, but he/she does not observe the inventory position nor the sales of the retailer. This class of problems are called *dynamic adverse-selection models with hidden Markovian states*, and are typically hard to solve. However, the authors show that under exponential demand and when the cost parameters are in a certain critical region, the optimal infinite-horizon contract for the supplier is stationary: the supplier gives a take-it-or-leave-it offer to the retailer in which a fixed quantity can be purchased for a fixed amount.

In a controlled experimental environment, Croson and Donohue [45] study the benefit of sharing inventory information in the context of “the beer game.” First, they find that decision makers consistently underweigh the pipeline stock even when the normal operational causes (e.g., batching, price fluctuations, and demand estimation) are removed, and as a result the bullwhip effect persists. Will sharing inventory information help remove some of the variability? It turns out sharing inventory information has little effect on the orders of downstream chain members. On the positive side, inventory information seems to substantially reduce the variance of orders for upstream members.

The empirical evidence on the effect of sharing inventory information is relatively few, but the results are generally positive. Clark and Hammond [46] find a correlation of VMI practices with performance improvements. Kulp *et al.* [47] conduct an extensive study with the food and consumer packaged goods industry, and find that sharing retail store inventory levels provide benefit to the manufacturer’s profitability. So does such collaborative planning on replenishment initiatives such as VMI.

Value of Sharing Order Status Information.

What about knowing the status of orders in transit or in process? Will that bring any value at all? Before the advent of sophisticated information technology, this question is not that relevant since such information is plainly unobtainable. However, as technologies such as RFID and GPS systems are becoming widely available and are increasingly being deployed and utilized in recent years, it becomes interesting to ask what the value of having order status information is. Gaukler *et al.* [48] analyze such potential of knowing order progress information. In a traditional supply system, a retailer placing an order only knows the time of its order release and the distribution of its stochastic lead time before it arrives. Now, with new tracking technology such as RFID, the retailer is able to track the status and location of its orders. This not only helps the retailer in deciding when to order and how much to order, but also enables the retailer to place an emergency order in the event of a likely delay. They solve the optimal inventory control policy [within the class of (Q, R) policies] with such added visibility, and show that the cost savings could be significant, especially in supply chains where lead times are long and variable. See also Ref. 49 and the article titled 4.5.3.4 in this encyclopedia for related studies and recent developments on RFID technologies.

In another stream of research, Jain and Moinszadeh [50] consider the value of manufacturers sharing inventory availability information with retailers. In their model of a typical two-tier serial supply chain, the manufacturer informs the retailer whether the product will be backordered before the retailer places its order. By doing so, the manufacturer shares information on inventory availability in the manufacturer’s finished-goods inventory. The retailer can then take advantage of such information by changing to a new ordering policy. But does the manufacturer have an incentive to share inventory availability information? The authors reveal that indeed, sharing such information will induce the retailer to increase its order rate.

Lead Time Information

Mainstream inventory optimization models have long embraced the uncertain nature of lead times. As a result, we know quite a lot about what to do when precise lead time information is not available in a system. For example, Song and Zipkin [51] studied a single-location inventory system of, say, a retailer, whose order lead time was random and followed a Markov process. Given that the retailer is able to have the lead time information for each period before it places an order, the authors show that a state-dependent base-stock policy is optimal.

But what if the retailer does not have such lead time information? What is the value of having such information? Chen and Yu [52] study this question. The authors compare two scenarios: one without information sharing, and the other with information sharing as in Ref. 51. Without information sharing on lead time information, the retailer can only infer current lead time from past order data in making replenishment decisions, whereas if the supplier cares to share order lead time information, the retailer can then implement the optimal state-dependent base-stock replenishment policy. They find that the value from sharing lead time information can be quite high, especially for high volume items.

Cost Information

In the past, it has generally been assumed in supply chain research that the cost structure of supply chain parties (e.g., cost of manufacturing, distribution, and selling for each stage of a supply chain) is public knowledge. In practice, however, supply chain parties often do not have perfect information on the other parties' costs. Recent research has challenged this assumption, and has since made substantial progress by incorporating asymmetry cost information.

Supply Chain Coordination under Information Asymmetry. Ha [53] studies a supply chain with a buyer and a supplier, but the marginal cost information of the buyer is unknown to the supplier. In order to induce truthful information, the supplier offers a

menu of contracts to distinguish the different buyer types. It is shown that because of information asymmetry, supply chain profit-maximizing solution is not attainable with a linear price contract. Corbett and de Groote [54] provide another example of screening contract in the context of a two-stage economic lot-sizing problem, where the buyer's cost information is private. Chen [15] studies a buyer who sources from multiple suppliers whose costs are only privately known. The author solves for an optimal procurement method, which is a quantity-payment schedule. This contract is auctioned off among the suppliers, and the winner can choose any quantity to deliver and gets paid according to the pre-announced payment schedule.

Recently, researchers began to study the impact of asymmetric cost information in a repeated relationship setting. Taylor and Plambeck [55] study a repeated capacity procurement game with one customer and one supplier. In their model setting, production cost is uncertain and therefore *ex ante* binding contracting is infeasible. They identify an optimal "relationship contract" that maximizes the customer's expected profits. Taylor and Plambeck [56] further study two simple forms of relational contracts, where the buyer can either promise to pay a specific price, or can promise to purchase a specific quantity. These contractual arrangements are both easy to implement, and the authors show that which option is optimal to the buyer depends on the production and capacity cost, as well as the discount factor.

Lee *et al.* [57] study a finitely repeated game. The setting is similar to the "selling to the newsvendor" model described in Ref. 58, except that the buyer's cost information is private, but they have opportunities to transact repeatedly. They find that the buyer's "information advantage" persists in the initial phase of the repeated game. However, as the game goes on, such an information advantage gradually dissipates, and the buyer starts to randomize between acceptance and rejection of the contract. Therefore, his/her private information is revealed in a probabilistic fashion. The supplier's long-run equilibrium strategy is of a threshold type: he/she starts with offering a low selling

price and keeps doing so until his/her belief about the buyer's type is over a threshold. These results indicate that repeated supply chain relationships have significantly different dynamics than those observed in a one-shot supply chain relationship.

Sharing Information about Product Development

Product development sits at the top of a supply chain. Therefore, it is relevant to study information sharing that is related to product development. There are two dimensions to this. The first is information sharing within the process of product development. There, the research question is how to best share information in order to come up with successful products with faster lead times. The second dimension is about the value of sharing information about product development, with other echelons of the supply chain. Below we review both areas of research.

The difficulty in sharing product information within the product development functional area is similar to what is observed in sharing forecast information. In both environments, the sharing of preliminary information is a common practice. Development teams frequently begin their work on a new product prior to receiving detailed design specifications from the customer and/or from the market research department. Therefore, how to utilize preliminary information is a central question. In this line of research, Krishnan *et al.* [59] and Loch and Terwiesch [60] model the situation faced by a concurrent engineering team where an information-receiving development activity must decide on how to rely on the preliminary information provided by the information sender. The information receiver always wants to start early, in an attempt to gain from parallel task execution. Starting early, however, uses a lower quality of information and thus has a higher likelihood of costly rework. Consequently, the information receiver faces the dilemma "Rush and be Wrong or Wait and be Late" [61]. This fundamental trade-off is similar to the supplier's problem as described above. These studies suggest that the time a project should commit resources, based on preliminary information, should be delayed

if the information received is still unstable or if experience from similar projects suggests that the information is likely to change in the near future.

Somewhat surprisingly, there has been little OM research identifying the value of sharing product development-related information with other stages of supply chains. This can be an interesting topic as in practice, firms take very different approaches. Take product preannouncement, for example. In the high-tech industry, it is well known that there are firms who never give product announcements (e.g., the famous Apple secrecy), and there are others who tend to preannounce their pipeline products well ahead of time (e.g., Microsoft). What is the impact on their supply chains? How to coordinate production and distribution under these different strategies? These are the questions that analytical modeling can help answer. On the other hand, empirical evidence seems to argue for the more open approach. For example, Kulp *et al.* [47] study the food and consumer packaged goods industry, and find that when manufacturers collaborate closely with their retailers and share product development-related information, they experience enhanced profit margins.

Accuracy of Information Shared

So far we have assumed that information shared in supply chains is accurate. Is that a universally valid assumption? Empirical evidence suggests not. We refer readers to article (See *Inventory Record Inaccuracy in Retail Supply Chains*) in this encyclopedia for an in-depth discussion, but here we briefly mention a few recent studies. Raman *et al.* [62] find that data inaccuracy persists in the retailing inventory, which results in substantial operational inefficiency and profit loss. DeHoratius and Raman [63] study inventory record accuracy with one nation-wide retailer, and find that 65% of the records have some forms of inaccuracy.

Recent analytical research has taken notice, and has begun to address this issue. Kok and Shang [64] study an inventory system with inaccurate records. A manager can conduct costly inventory inspection at the beginning of each period to correct

record inaccuracy. They show that an inspection-adjusted base-stock (IABS) policy is optimal for the single-period problem, and is nearly optimal for the finite-horizon problem. Lee and Özer [49] study the value of RFID technology in improving information accuracy. They distinguish inventory records from actual inventory, and attribute inventory inaccuracy to two causes: inventory misplacement, and transaction errors. They also show that RFID technologies allow for better control and can reduce inventory-related costs. Using a classical multiperiod periodic review inventory model, DeHoratius *et al.* [65] model inventory inaccuracy as an invisible demand process. As a result, the decision makers have imperfect information of the true inventory status. They propose a Bayesian information updation method and derive corresponding replenishment policies that are shown to effectively recoup much of the cost incurred by inventory record inaccuracy.

SUMMARY AND FUTURE RESEARCH

We have made great strides in understanding and managing information sharing in supply chains. However, supply chain innovation constantly brings about new questions and challenges. Here, we conclude with a few thoughts on some emerging issues as well as some less-explored research areas:

1. *Innovation in Supply Chain Structure.* OM literature typically deals with various supply issues under a given supply chain structure (i.e., a serial supply chain, or a distribution network). With the help of information technology, business models are undergoing tremendous innovations. This includes innovations in supply chain structures. For example, there are situations where customers may not know exactly who their suppliers are. In this setting, it is not clear if sharing information will necessarily lead to better outcome. With more innovations on supply chain structure, more research in this area will be needed.
2. *Information Technology and New Information.* With information technology, it is possible to have access to information at a more granular level. For example, it may be possible to track product-related information at every step in the supply chain. This may mean significant cost saving for perishable products. For example, Ferguson and Ketzenberg [66] analyze the value of sharing product age information. In their model, a retailer sells a perishable product to consumers and receives replenishment from a supplier. The product lifetime is fixed once received by the retailer, but the age of replenished items varies stochastically over time. Because the product is perishable, any unsold inventory remaining after the lifetime elapses must be discarded. With information sharing, the retailer then is informed of the product age, prior to placing an order, and is able to make better ordering decisions. They find that the retailer benefits the most from information sharing when the variability of demand is high, product lifetimes are short, and the cost of the product is high.
3. *Information in Service Supply Chains.* Service is dominant in today's economy. However, we do not have as much knowledge in understanding service supply chain as we do with inventory supply chains. More research is needed to study the connection between literature in the two areas, and what is different in information sharing in service supply chains. For example, what information should be shared, and what is the value of sharing such information in health-care delivery systems? We do not have good answers to such questions yet. An important distinction of service supply chains is their interaction with customers. Hence, information sharing with customers in addition to supply chain parties adds another interesting dimension of complexity. Much more research can be done in

better managing information to better customer experience and improve system efficiency.

4. *Empirical Research.* Finally, we need more empirical work analyzing and understanding the benefits of information sharing in supply chains, the drivers of such benefits, and what are the significant facilitators and mediators in realizing those benefits. Among the various areas of literature on information sharing we reviewed above, empirical research is distinctively lacking in many of them. With more empirical evidence in helping us answering those questions thoroughly, we will be able to identify new research questions and spur further analytical research.

INITIAL TRANSIENT PERIOD IN STEADY-STATE SYSTEMS

K. PRESTON WHITE JR

Coventry, UK

THE PROBLEM

The problem of the *initial transient*, also known as the *start-up* or *warm-up* or *initialization-bias problem*, arises in estimating the limiting distribution of a nonterminating stochastic process from output generated by one or more replications of a discrete-event simulation. Because the steady-state operating regime does not offer natural boundary conditions for starting or stopping simulation runs, initial conditions typically are chosen for convenience and terminating conditions are sought which provide satisfactory point and interval estimates. It is well known that arbitrary initialization can introduce bias in estimators of the limiting statistics.

In this article, we discuss the problem of the initial transient and outline methods for dealing with the problem. We focus on two specific methods: one graphical (Welch's method) and the other heuristic (MSER-5).

A PRACTICAL EXAMPLE

Figure 1 provides an example of the initial transient in a model of a real system. The simulation model represents a user support help desk [1]. Requests for support arrive via telephone, email, and face-to-face contact. Some requests can be dealt with immediately, but others queue for service or require a call-out. This leads to delays of a week or more in some cases. The graph shows the total waiting time

for the first 500 calls (entities) to leave the simulation model and the cumulative average waiting time. Because the model starts (for convenience) in the infrequent state of no calls in the system, a clear bias exists in the early observations.

A SIMPLE EXAMPLE ILLUSTRATING ISSUES AND NOTATION

The fundamental issues can be elucidated using the straightforward example of an M/M/1 queue for which we are interested in estimating interval statistics for the mean number in system from a simulation experiment. The output of a single simulation run is a realization of the discrete-state, continuous-parameter stochastic process $\{Y_i; i = 0, 1, 2, \dots, n\}$, where $Y_i = Y(t_i)$ is the i th sequential observation from a simulation with run length n and initial condition $Y_0 = y_0$. The sample mean and large-sample variance are

$$\bar{Y}(n | y_0) = \sum_{i=0}^k \omega_i Y_i,$$
$$S^2(n | y_0) = \sum_{i=0}^k \omega_i Y_i^2 - \bar{Y}(n | y_0)^2,$$

where the weight $\omega_i = 1/(n + 1)$ and $k = n$ for variables which are tallied (such as customer waiting times for the help-desk example), or $\omega_i = (t_{i+1} - t_i)/(t_n - t_0)$ and $k = n - 1$ for variables which are time-averaged (such as the number in system for the M/M/1 queue). Since the process generating these observations is ergodic, these are consistent estimators for the steady-state mean θ and variance σ^2 , independent of the choice of initial condition, that is, $\lim_{n \rightarrow \infty} \bar{Y}(n | y_0) = \theta$ and $\lim_{n \rightarrow \infty} S^2(n | y_0) = \sigma^2$, $\forall y_0 \geq 0$. However, because the observations are sequentially correlated, for finite n and arbitrary $y_0 \neq \theta$, both estimators are biased. Thus, there is bias in both the location (accuracy) and

Figure 1. The user support model, waiting time in the system by entity as it departs the system and the cumulative average waiting time.

Figure 2. The time-domain effects of initial conditions and autocorrelation on the running estimate of mean number in system for two M/M/1 queues differing in traffic intensity.

width (precision) of the estimated confidence interval on the mean.

This is illustrated in the time-domain in Fig. 2. Each panel shows the sequence $\{y_i; i = 0, 1, 2, \dots, n\}$, the number in system

for an M/M/1 queue as a function of the observation number for a single simulation run, where observations are made at each change of state. The mean arrival rate is $\lambda = 1$ and the terminating event

Figure 3. The frequency-domain effects of initial conditions and autocorrelation on the running estimate of mean number in system for two M/M/1 queues differing in traffic intensity.

is 10,000 departures, resulting in a run length $t_n \cong 10,000$ with $n \cong 20,000$ arrival and departure events. Also shown is the corresponding cumulative sample mean, the sequence $\{\bar{y}(i | y_0), i = 0, 1, \dots, n\}$. The queues in panels (a) and (b) have traffic intensities of $\rho = 0.7$ and these queues are initialized, respectively, at $y_0 = 90$ (a rare event, with $\Pr(Y_i \geq 90) = 6.86 \times 10^{-15}$) and $y_0 = 4$ (the approximate steady-state mean). The queues in panels (c) and (d) have traffic intensities of $\rho = 0.9$, initialized respectively at $y_0 = 90$ ($\Pr(Y_i \geq 90) = 6.86 \times 10^{-5}$) and $y_0 = 9$ (the steady-state mean). The bias introduced by the rare initial conditions is clear for both queues; the severity of this bias is clearly greater for the queue with higher traffic intensity (greater autocorrelation).

These effects are perhaps even more apparent in the (relative) frequency domain, as shown in Fig. 3. The stationary state for the queue is distributed geometrically, $Y_{ss} \sim \text{Geom}(1 - \rho)$, with mean $\theta = \rho/(1 - \rho)$ and

variance $\sigma^2 = \rho/(1 - \rho)^2$. Panels (a) and (c) compare the histograms of the estimated distributions for both the unbiased and biased initial conditions (for the entire run) to the probability mass function (pmf) of this theoretical distribution. These comparisons are repeated in panels (b) and (d), where the steady-state probabilities are now plotted on a logarithmic scale. This transforms the geometric pmf into a straight line and exaggerates the differences between the estimated and theoretical distributions at lower probabilities.

This example illustrates the fundamental issue. Every state is *positive recurrent*, $\Pr(Y_i = y) > 0$ for all $y \geq 0$ at steady state, and therefore the states themselves are *not* transient in the usual sense. For both the unbiased and biased cases, however, there is a transient period associated with the *sample mean*, $\bar{Y}(i, y_0)$, during which a sufficiently large number of observations must be collected for the sampling distribution

to approximate the true stationary distribution. For the biased case, there is also a transient period associated with the system state, Y_i , during which the state decreases from an improbable artificial initial value to subsequent values more representative of the steady-state operating regime. *Both* transients are prolonged by increasing autocorrelation in the values of the state. The duration of the mean transient is considerably longer than that of the state transient, because of the additional autocorrelation induced by calculating the cumulative mean.

With these observations, it is apparent that there is some minimum run length required to reduce the sampling error to an acceptable level for estimation of any statistic. This minimum run length increases with the degree of autocorrelation and is an inescapable artifact of the system under study. This minimum run length also increases with the increasing rarity of the initial value of the state. The problem of the initial transient, therefore, is to reduce the run length required to yield accuracy and precision in the sample statistics comparable to that in the unbiased case; or, alternatively, for a given computing budget, to improve the accuracy and precision in the sample statistics by removing the contribution of the state transient.

Dealing with the Problem

The problem of the initial transient has been studied extensively and two principle approaches exist for its mitigation. *Intelligent initialization* attempts to select initial conditions that are representative of the steady-state operating regime for each simulation run. In the simple case of the M/M/1 queue, for example, this implies initializing the number in system with a value close to the steady-state mean or mode [2,3]. If practical, this approach is always wise.

Banks *et al.* [4] offer two strategies for intelligent initialization—(i) observation and collection of data from the system under study, or a similar system, if such systems exist and (ii) solution of simplified, analytically tractable models approximating the

system or subsystems. Information regarding the choice of more representative initial conditions also may be available from pilot simulation runs undertaken during model development and verification. If the frame for output analysis employs multiple replications, Kelton [5] suggests that initial conditions be chosen at random from simple (uniform or binomial) probability distributions, as crude approximations to the stationary distributions. The parameters for these distributions can be based on expert opinion.

Intelligent initialization clearly has its limitations. Systems or comparable systems often simply do not exist. When these do, the time and expense of collecting the data required for intelligent initialization may be prohibitive. Analytically tractable models that adequately capture steady-state response also may be unavailable, or at least difficult to determine with any degree of confidence or fidelity.

Deletion or truncation uses the simulation itself to select initial conditions. This is accomplished by allowing the simulation to *warm-up* by running the simulation for some period of time, until a more representative state is achieved as the system finds its way into a more typical steady-state operating regime. Observations collected during this period are *deleted* in the computation of statistics for the remainder of the simulation run. This second approach can be employed as an alternative to intelligent simulation, or in conjunction with a judicious choice of initial conditions.

Using deletion, the steady-state mean estimator is

$$\bar{Y}(n, d | y_0) = \sum_{i=d+1}^k \omega_{i,d} Y_i,$$

where d is the length of the warm-up period and $\omega_i = 1/(n + 1 - d)$ and $k = n$ for variables which are tallied, or $\omega_i = (t_{i+1} - t_i)/(t_n - t_d)$ and $k = n - 1$ for variables which are time-averaged. The central issue in the deletion approach is to determine an appropriate value for d . If the period is too short, the effects of initialization may be reduced, but not eliminated. If the period is too long,

useable observations are discarded and the precision of the estimate suffers.

A very large number of methods have been proposed for determining the length of the warm-up period. These can be classified into five types [6]:

- *graphical methods* that plot the sample path and determine the truncation point by visual inspection;
- *initialization-bias tests* that directly identify bias in the sample path;
- *heuristics* that apply simple rules to the sample path;
- *statistical methods* that apply basic statistical principles (such as hypothesis testing) to the sample path;
- *hybrid methods* that typically combine graphical methods with heuristics.

Various methods have been proposed in each of these categories and are listed in Table 1. In addition to the original papers cited, surveys listed among the references provide further details and comparisons.

Graphical methods are almost certainly the most common in practice and one prevailing view is that visualization of the evolution of the output and statistics of interest is the easiest and most accurate strategy. Certainly, the human faculty for recognizing visual patterns should not be underestimated. To the extent practicable, individual and cumulative observations should be plotted and inspected visually as a part of any warm-up analysis.

Initialization-bias tests are not strictly the methods for identifying the warm-up period, but can be readily adapted to this end through repeated application to alternative truncated series. Heuristics and statistical methods are highly desirable, since these can be applied to suggest, refine, validate, and in some instances automate the choice of a truncation point. Rules and procedures that can be automated are being incorporated in some simulation software and are particularly useful when a simulation study requires a large number of runs. Given the widespread use of graphical methods and the growing importance of good heuristics, examples of these

two approaches are provided in the following sections.

GRAPHICAL METHODS AND WELCH'S PROCEDURE

Welch's graphical procedure [6,51–53] has been advanced as a general approach to aid in visualization. The following development parallels Law [54], who also provides recommendations for choosing parameters for the procedure. The procedure relies on first averaging observations across m independent replications, where each replication has length n observations and the same initial value y_0 . The result is the averaged process

$$\left\{ \bar{Y}_i(y_0) = \frac{1}{m} \sum_{j=1}^m Y_{ij}(y_0), i = 0, 1, 2, \dots, n \right\},$$

where $Y_{ij}(y_0)$ is the i th observation from the j th replication. Averaging preserves the transient mean, $E[\bar{Y}_i(y_0)] = E_j[Y_{ij}]$, while reducing the transient variance by a factor of m , $\text{Var}[\bar{Y}_i(y_0)] = \text{Var}_j[Y_{ij}(y_0)]/m$, for all $j = 1, \dots, m$. Five to ten replications are recommended initially.

Secondly, the averaged process is smoothed by a moving average with a window of length w , where w is a positive integer such that $w \leq \lfloor n/4 \rfloor$, as follows:

$$\bar{Y}_i(w, y_0) = \begin{cases} \frac{\sum_{s=-w}^w \bar{Y}_{i+s}(y_0)}{2w+1}; & \text{if } i = w, \dots, n-w, \\ \frac{\sum_{s=-(i-1)}^{i-1} \bar{Y}_{i+s}(y_0)}{2i-1}; & \text{if } i = 0, \dots, w-1. \end{cases}$$

The intent is to filter high-frequency oscillations, leaving a smooth moving-averaged process

$$\{\bar{Y}_i(w, y_0), i = 0, 1, 2, \dots, n-w\},$$

which closely approximates the transient cumulative mean for m sufficiently large.

Finally, the moving-averaged process is plotted and the length of the warm-up period

is determined by visual inspection as the point at which the process “flattens out.” If this process is not sufficiently smooth to make a determination, w is increased and the moving-averaged process is recalculated. If w is at its limit and the process still is not sufficiently smooth, additional replications are required and the moving-averaged process again is recalculated. If the process does not appear to flatten, then n must be increased, or it is possible that the model does not reach a steady state.

Welch's procedure can be effective, but expensive to implement. If the process is highly variable, the run length n and the number of replications m required to capture the transient and achieve a smooth moving-averaged process can be large. If the computational intensity of the simulation is also large relative to the computing budget, then the $n \times m$ observations required to develop a clear understanding of the artificial initialization transient might be applied more effectively to observing the steady state. Additionally, visual determination of d remains subjective, as in all purely graphical methods, and cannot be directly automated.

Figure 4 illustrates these issues. Welch's procedure was applied to the M/M/1 queue with traffic intensity of $\rho = 0.9$ discussed above, with $n \cong 10,000$ events, $m = 10$ replications, and a window of $w = 1500$. The number in system is plotted for each replication as a function of the observation index i , as are the average and moving-averaged processes. Inspection of the moving-averaged process does not clearly indicate the length of the warm-up period. Indeed, what we might infer from this application is the truth that the cumulative mean approaches its steady-state value asymptotically from above. This is doubtless and very useful to know, but comes at considerable computational expense ($n \times m = 100,000$ observations). Moreover, the central issue of how to select a truncation point for subsequent output analysis remains unclear.

HEURISTICS AND MSER

Heuristics are the oldest nongraphical approaches to determining the length of the warm-up period. In many instances, these are based on the calculation of what

Figure 4. Results of the application of Welch's procedure (10 replications and a window of 1500) for mean number in system for an M/M/1 queue with traffic intensity $\rho = 0.9$.

amounts to a visual cue (such as the state trajectory crossing the mean trajectory), which is easy to understand and equally easy to compute. In a recent study, Hoad *et al.* [7] investigated the methods listed in Table 1. On the basis of criteria that included accuracy and robustness, simplicity, potential for automation, number of estimated parameters, and computation speed, they selected the MSER-5 heuristic as the most suitable for automation.

The original MSER [27,55] determines the length of the warm-up period by solving the following optimization problem:

$$\begin{aligned} d^* &= \arg \min_{n \gg d \geq 0} [MSER(n, d | y_0)] \\ &= \arg \min_{n \gg d \geq 0} \left[\frac{1}{(n-d)^2} \sum_{i=d+1}^n \right. \\ &\quad \left. \times (Y_i - \bar{Y}(n, d | y_0))^2 \right]. \end{aligned}$$

The intuition is that this choice minimizes the width of marginal confidence interval on the mean. While this interval is calculated using the sample variance of the reserved sequence (the sequence remaining after truncation) as an estimator for the variance, Franklin and White [31] have shown that substituting an unbiased estimator is less efficient and does not improve the performance of the heuristic. Because the state transient is much shorter than the mean transient, truncation at d^* in effect eliminates initialization bias and (approximately) minimizes the mean-squared error in the estimate of the mean.

MSER- m [30,56] is an improvement in MSER, which replaces the output series $\{Y_i; i = 0, 1, \dots, n\}$ with the series of batch means $\{Z_j, j = 0, 1, \dots, \lfloor n/m \rfloor\}$, where

$$Z_j = (1/m) \sum_{p=1}^m Y_{m(j-1)+p}. \quad (1)$$

Figure 5. Results of the application of MSER-5 for mean number in system for an M/M/1 queue with traffic intensity $\rho = 0.9$.

The length of the batch is somewhat arbitrary, but the value $m = 5$ has shown to yield superior results over a wide range of test problems.

Figure 5 illustrates the application of MSER-5 to the M/M/1 queue with traffic intensity of $\rho = 0.9$ with $n \cong 10,000$ events. In addition to the output sequence and cumulative mean, panel (a) also shows the truncated mean $\bar{Y}(n, d | y_0)$ and $\text{MSER}(n, d | y_0)$ statistic as functions of the truncation point $d = i$. The minimum value of the statistic over the initial component of the run obtains at $d^* = 1607$ ($t_{d^*} = 781.8$), with $Y_{d^*+1} = 18$ as the initial value of the reserved sequence and $Y(n, d^* + 1 | y_0) = 8.871$ as the truncated point estimate of the mean.

In addition to the biased, unbiased, and theoretical log-densities, panel (b) shows the log-density of the reserved sequence for the MSER-5 truncation point. Clearly the state transient has been removed. Equally clearly, there remains a substantial mean transient, which overrepresents observations in the range of 21–47 and causes a high estimate of the mean for this run. This is true for the unbiased and biased sequences as well, and is not an artifact of initialization. Given the high autocorrelation, a significantly longer run length is required to provide reasonable precision in the estimate.

HYBRID WELCH/MSER

A principle shortcoming of Welch's procedure—that it yields a subjective determination of the truncation point by visual inspection—can be overcome by applying a heuristic to the moving-averaged process. For example, Fig. 6 plots the moving-averaged process from Fig. 4, together with the truncated mean and MSER statistic for this process. MSER recommends a truncation point of $d^* = 6653$, corresponding to a value of $\bar{Y}_i(w, y_0) = 7.9212$. Adopting an initial condition of $y_0 = 8$ for subsequent output analysis is a very reasonable choice.

How many Replications?

There are two standard frameworks for steady-state output analysis. *Replication/deletion* uses m independent replications, deleting the mean transient from each. Its advantage is that the mean estimates from each replication are uncorrelated and easily computed. Its disadvantage is inefficiency. The mean transient is repeated in each replication at a cost of $d \times m$ deleted observations, if the same warm-up period is used for each replication (which is typically the case). This is compounded by the need for a conservative value for d , which is sufficiently large to capture the transient for each replication.

Figure 6. Results of the application of MSER to the moving-averaged process developed using Welch's procedure for an M/M/1 queue with traffic intensity $\rho = 0.9$ initialized at 90 in system.

Figure 7. Results of the application of MSER-5 to a single long run for an M/M/1 queue with traffic intensity $\rho = 0.9$ initialized at 90 in system.

The alternative to replication/deletion is a *single, long run*, with the advantage that the transient is identified and deleted only once. The disadvantage is the need to construct an unbiased estimator for the variance, which corrects for autocorrelation of the observations. This is most often accomplished by the method of *batch means*. The reserved time series is divided into some number (typically 20–40) sequential batches, the mean is computed for each batch, and the variance of the batch means is used to estimate the confidence interval on the mean. This approach is effective if the batches are sufficiently large to result in uncorrelated batch means. While many authors express a strong preference for replication/deletion approach, the method of batch means can be vastly more efficient [57].

We illustrate this observation by applying MSER directly to one long run of the example M/M/1 simulation, given the same computing budget of $n \cong 100,000$ observations employed in the determination of a warm-up period applying Welch's procedure. The results are shown in Fig. 7. MSER-5 recommends a truncation point of $d^* = 3350$, approximately half that determined previously for the moving-averaged sequence. Applying batch means to the reserved sequence with 20 batches, the estimated 95% confidence interval on the mean is

$\bar{Y}(n, d | y_0) = 9.5061 \pm 1.774$. Note that in applying Welch's procedure, the entire budget was expended in developing a clear sense of the initial transient, in order to determine a suitable initial condition for further output analysis. In contrast, using this same budget to generate a single, long replication, and applying MSER-5 to the result, yield point and interval estimates of the mean without additional computation. In our research, this economy has been consistent across all instances of a wide range of test problems.

CONCLUSIONS

This article describes the problem of the initial transient that arises when estimating the limiting distribution of a nonterminating stochastic process. Concepts are explored with reference to simple M/M/1 queueing model with an artificially induced initial bias. A range of solution methods have been proposed and here we explore two such approaches, graphical and heuristic. We also demonstrate how these methods might be combined. Results from test problems consistently show that truncation of output data from a single long run is more economical than the replication/deletion approach for nonterminating simulations.

INSPECTION GAMES

RYUSUKE HOHZAKI
Department of Computer Science
National Defense Academy,
Yokosuka, Japan

INTRODUCTION

Dresher [1] began the inspection game to analyze the treaty of arms reduction in 1962. In the field of compliance of treaties or laws, the expansion of the inspection game has three phases in accordance with the situation of international relations in the world. Dresher's work belongs to Phase I in the 1960s under the commission of the US Arms Control and Disarmament Agency (ACDA). Dresher proposed a recursive game to analyze the effectiveness of on-site inspections for the treaty. Maschler [2] generalized Dresher's modeling. They considered the game where a player called *a violator* wished to violate the treaty in secret for his national interest, and the other player called *an inspector* wanted to deter illegal behaviors of the violator by effective inspection. In their models, the violator must pay one of the penalties if his violation is exposed by an inspection but he can escape the exposure by side payment of penalty q . Dresher discussed special cases of $q = 1/2$ and $q = 1$, and Maschler did a general case of $0 \leq q \leq 1$. As well as Dresher and Maschler, Kuhn [3] contributed to the game-theoretical analysis on Nuclear test ban treaty in Phase I.

Phase II has a span from the late 1960s to the 1980s. In this phase, they discussed the compliance of the Non-Proliferation Treaty for Nuclear Weapons. The International Atomic Energy Agency (IAEA) is an international organization founded in 1957 to promote safe, secure, and peaceful nuclear sciences and technology all over the world. The treaty on the Non-Proliferation of Nuclear Weapons (NTP) makes use of the

inspection the IAEA supplies to prevent the spread of nuclear weapons and technology. Bierlein [4], Jaech [5], Avenhaus [6], and Bowen and Bennett [7] promoted the application of game theory to such treaties as the NTP.

In Phase III after the Cold War, the inspection game was developed to deal with new disarmament treaties, for example, the treaty on intermediate nuclear forces and the treaty on conventional forces in Europe, in the mid-1980s. Brams and Davis [8], Kilgour [9], Ruckle [10], and Avenhaus and Cauty [11] belong to this phase.

The level on frequency of inspections by the IAEA is precisely prescribed in agreement such as the Information Circulars 153. On the basis of its scientific rules, most of the inspections were carried out in Japan, Germany, and Canada until 1993 because these countries have many nuclear-powered electric plants. These countries were believed to have no intention or no motivation to develop nuclear weapons. On the other hand, the inspection cost accounts for a large part of the annual budget of the IAEA, and the inspections were thought to be a waste of the money. After that, there occurred serious problems such as Dr. Khan's black market and we had the suspicion that some countries were developing nuclear weapons using nuclear technologies in black market. Through these problems, the IAEA changed its policy and tried to strengthen the safeguard system by additional protocols and NTP Comprehensive Safeguard Agreement. Some researchers analyzed the intention of inspectees to make illegal actions from the game-theoretical point of view, for example, Avenhaus [12], Avenhaus and Kilgour [13], Avenhaus and Cauty [14], and Hohzaki [15].

Dresher's research was branched out to the so-called smuggling game. Thomas and Nisgav [16] extended Maschler's model to a game with Customs and a smuggler, in which Customs patrols for illegal actions of the smuggler by using one or two patrol

boats. They formulated the problem into a multistage recursive game and adopted a simple numerical method to repeat solving a one-stage matrix game step-by-step. The smuggling game reflects real serious problems that the United States faced during the 1980s through the 1990s. The US Customs Service, the Drug Enforcement Agency, and the Department of Defense were eager to interdict the smuggling of drug into the United States by inspection or surveillance around the border between the United States and other countries. At that time, they focused on network interdiction games; for example, see Mitchell and Bell [17], Caulkins *et al.* [18], and Washburn and Wood [19]. Washburn and Wood constructed their model on a network and applied graph theory as well as game theory to solve the problem. The network interdiction problem could be applied to many problems in the real world, such as tactical air strikes, interdiction of drug invasion, controlling infections in a hospital, chemically treating raw sewage, or flood control. Many researchers have studied on this topic, such as McMasters and Mustin [20], Ghare *et al.* [21], Fulkerson and Harding [22], Golden [23], Gal [24], Wood [25], and Whiteman [26]. The ambush game is a model that is similar to the interdiction game [27].

Not related to any network structure, Baston and Bostock [28] first gave us a closed form of equilibrium point for the typical type of inspection game as an extension of Dresher's model. Furthermore, they modified the perfect-capture assumption, that Customs certainly captures the smuggler when both players meet, to the nonperfect-capture model. They succeeded in solving the game by introducing capture probability depending on the number of patrol boats. However, the opportunity for the smuggler to ship its cargo of contraband is still assumed to be once at most, as assumed in the preceding papers. Garnaev [29] extended their work to a model with three patrol boats.

Compared with these studies, Sakaguchi [30] introduced the assumption that the smuggler possibly takes several actions in the perfect-capture model. His model is a

kind of repeated game with several opportunities of smuggling and then the value of the game is given by multiplying the value of the once-opportunity game by the number of opportunities. Ferguson and Melolidakis [31] is an extension of Sakaguchi's model. They assumed that the smuggler can get rid of the capture by paying some cost $q (\leq 1)$. He must pay unit cost 1 on being captured but he loses nothing if not captured. Hohzaki *et al.* [32] also extended Sakaguchi's model such that the capture of smuggler terminates the game, and the encounter of the smuggler and Customs stochastically results in one of capture, success of smuggling, or no-event. Almost all researches adopted the assumption that the smuggler has two options (smuggling or not-smuggling) as his strategy. Hohzaki [33] first analyzed the smuggling game with the smuggler's decision on the amount of contraband. In almost all past models, they assumed that players know the behavior their opponents took in the past. If information about their opponents is perfectly hidden to competitors, players have no chance to change their strategies, and therefore the problem would become a one-shot game. Hohzaki and Maebara [34] considered a one-shot smuggling game during a finite number of days without getting any information.

In all models surveyed so far, the information acquisition is symmetric between players. Harsanyi [35] made us notice that information is crucial to the results of the game, and proposed the concept of complete information and incomplete information. The concept has been applied to a variety of game models. In the smuggling game, it would be natural that players acquire information about their opponents in an asymmetric manner because Customs is generally thought to be a public organization and the smuggler would be a secret society. Under the situation, the information acquisition must be asymmetrical between players. Hohzaki [36] first dealt with a smuggling game with asymmetric information, where Customs decides to patrol or not to patrol without any smuggler's information, but the smuggler chooses his strategy, knowing the past decision of Customs. He proposed a

methodology to derive Bayesian equilibrium and evaluated the value of information.

We have traced the history of the inspection game stemming from Dresher's work. From this point, we first focus on some models of the smuggling game and explain its basics and methodology to derive Nash equilibriums while paying attention to the value of information. And we look at the models of the interdiction game and the ambush game.

A BASIC MODEL OF INSPECTION GAME WITH MULTIPLE STAGES

We consider the following two-person zero-sum (TPZS) game with Customs and a smuggler, taken in Reference [32], because it is more general and more applicable than Dresher's original modeling.

- A1. Customs and a smuggler compete with each other during N days, on each of which two players take an action once at most. We denote each stage by the number of residual days until the last day like $N = \{N, N-1, \dots, 1\}$.
- A2. Customs can afford to patrol K times at most and the smuggler can smuggle L times at most. In the case of $K > N$ or $L > N$, players lose excess opportunities of patrolling for Customs and smuggling for the smuggler.
- A3. At each stage, Customs has two options: patrol (P) or not-patrol (NP). The smuggler also has a two-option strategy: smuggling (S) or not-smuggling (NS).
- A4. If the smuggler smuggles and Customs dispatch a patrol boat on the same day, Customs can capture the smuggler with probability p and, at the same time, the smuggler succeeds in smuggling with probability q . With the residual probability of $1 - p - q$, there happens nothing. In the case of no patrol, the smuggler successfully fulfills his smuggling.
- A5. Customs gains reward $\alpha > 0$ by the capture of the smuggler but loses reward 1 on success of smuggling by the smuggler. We assume $\alpha p - q > 0$

because the smuggler dare not smuggle on the patrol day of Customs.

The payoff of the game is zero-sum, which means that the reward of Customs is the same amount of loss for the smuggler and vice versa. We define the payoff of the game by the Customs' reward.

- A6. If Customs does not capture the smuggler at a stage, the game transfers to the next stage, and the number of stage decreases by one. The game ends on capture of smuggler or at the last stage with no residual day.
- A7. Assumptions A1 through A6 are common knowledge for both players. Each player knows the strategies taken by his opponent at the past stages.

Our TPZS game model is slightly complicated than Baston and Bostock's model or Sakaguchi's model. However, the methods or formulations for equilibrium points are very similar, although the formulations have individual difficulties for their solutions. The multistage inspection game is usually solved through the construction of a recursive game and a system of recursive equations or difference equations. Now let us proceed to the next step to construct the recursive game for our model.

By $\Gamma(n, k, l)$, we denote the game starting from Stage n , at which Customs has k opportunities to patrol and the smuggler can smuggle l times at most, and by $v(n, k, l)$, we denote the value of the game $\Gamma(n, k, l)$. Considering each combination of two players' strategies at Stage n and its resultant situation, we can represent the value $v(n, k, l)$ by the value of the following recursive 2×2 matrix game.

$$v(n, k, l) = \text{val} \begin{pmatrix} \alpha p - q + (1-p)v(n-1, k-1, l) & v(n-1, k-1, l-1) \\ -1 + v(n-1, k, l-1) & v(n-1, k, l) \end{pmatrix}, \quad (1)$$

where val represents the value of its sequent matrix game. Two columns of the left and the right represent the smuggler's strategies: S and NS, respectively. The upper row and the

lower row represent the Customs' choices: P and NP, respectively. Taking the combination of P and S, for example, Customs can expect reward $\alpha p - q$ at the present stage. The game ends at this stage with probability p if the smuggler is captured; otherwise it steps forward to the next stage with probability $1 - p$ to transfer to a new stage game $\Gamma(n - 1, k - 1, l - 1)$. Other elements of the payoff matrix are also explainable.

Starting from initial conditions of $v(0, k, l) = 0$, $v(n, k, 0) = 0$, and $v(n, 0, l) = -l$ and using Equation 1, we can numerically calculate $v(n, k, l)$ for any n , k , and l . Hohzaki *et al.* [32] proved that four elements in Equation 1, substituted by four alphabets a , b , c , and d , have the following relation:

$$v(n, k, l) = \text{val} \left(\begin{array}{ccc} a & > & c \\ \vee & & \wedge \\ b & \leq & d \end{array} \right),$$

and that any optimal strategy always becomes a mixed one. The value of the game is given by $v(n, k, l) = (ad - bc)/(a - b - c + d)$, and the expression is regarded as a difference equation held between $v(n, \cdot)$ and $v(n - 1, \cdot)$. In some cases, we can solve the difference equation with respect to three indices n , k , and l , and have an analytical form of solution. In the case of $l = 1$, $v(n, k, 1)$ is given by

$$v(n, k, 1) = - \binom{n-1}{k} / \sum_{r=0}^k (\alpha p - q)^{k-r} \binom{n}{r} \quad (2)$$

In this case, the probability for Customs to patrol is kept the same through all stages by his optimal strategy so that the smuggler cannot anticipate the most risky day for him when Customs is most likely to patrol. The solution 2 is a generalization of the results that Baston and Bostock [28] and Sakaguchi [30] obtained. In other cases of $l > 1$, we can derive their results as special cases of our model by setting $\alpha p - q = 1$.

THE VALUE OF INFORMATION IN THE INSPECTION GAME

We have overviewed the general basic model of the inspection game in Section 2, where

both players choose their actions after knowing their opponents' past strategies. The information the players get makes a lot of effects on the results of the game, as Harsanyi [35] pointed out. Here, we take two models for analysis: a no-information model in which both players do not get any information about their opponents, and an asymmetric information model in which there occurs an asymmetry between the information of both players.

A Model with No Information

Let us first discuss the inspection game with no information. We precisely define the change of the assumption from the basic model in Section 2. We replace Assumption A7 with the assumption of no information, as follows.

- S1. Each player makes his decision at each stage without knowing any strategy of his opponent in the past. However, both players can recognize the occurrence of capture of the smuggler.

Even under Assumption S7, it is natural that both players distinguish between capture and no-capture, and the game steps forward to the next stage only if the smuggler is not captured. The small change of the assumption makes the problem a one-shot game because all players have no chance to revise their strategies in process of the game without any information to use and would make their decisions once in advance of the game. We derived a closed-form expression for the value of the multistage game in a special case in Section 2. For the one-shot game, we can pursue more elaborate methodology to derive equilibriums.

For all stages N , we denote an pure strategy of Customs by $\mathbf{x} = (x_N, x_{N-1}, \dots, x_1)$, where x_j is 1 for P and 0 for NP at the Stage j and satisfies $\sum_j x_j \leq K$, and a smuggler's pure strategy by $\mathbf{y} = (y_N, y_{N-1}, \dots, y_1)$, where y_j is 1 for S and 0 for NS at the stage j and has $\sum_j y_j \leq L$. For a combination of a Customs' pure strategy $\mathbf{x}$ and a smuggler's pure strategy $\mathbf{y}$, we can evaluate the payoff by

$$R(\mathbf{x}, \mathbf{y}) = \sum_{n=1}^N (1-p)^{T_n(\mathbf{x}, \mathbf{y})} y_n \{x_n(\alpha p - q + 1) - 1\}, \quad (3)$$

where $T_n(\mathbf{x}, \mathbf{y}) \equiv \sum_{j=n+1}^N x_j y_j$. $(1-p)^{T_n(\mathbf{x}, \mathbf{y})}$ indicates the survival probability of the smuggler until Stage n .

Because there are a finite number of feasible pure strategies for both of $\mathbf{x}$ and $\mathbf{y}$, we can numerically solve the matrix game with the payoff $R(\mathbf{x}, \mathbf{y})$ if we do not mind the size of the problem. However, this model looks interesting as an example of application of dynamic programming (DP) and probability theory such that each player estimates his opponent's mixed strategy $\mathbf{x}$ or $\mathbf{y}$ stage-by-stage by using the information of capture or no-capture. The smuggler who took S strategy at the present stage n might revise the estimated probability of Customs' taking strategy $\mathbf{x}$, denoted by $\rho(\mathbf{x})$, conditioned on no-capture by

$$\Gamma_n \rho(\mathbf{x}) = \frac{\rho(\mathbf{x})(1 - p x_n)}{1 - p \Pr(\text{Customs takes any strategy with } x_n = 1)}$$

at the next stage. On the other hand, the smuggler who took NS would not revise the probability $\rho(\mathbf{x})$ because the capture never occurs. By DP formulation, we can find the rational behavior of the smuggler based on the revised probability on the Customs' mixed strategy stage-by-stage and finally derive an optimal Customs' mixed strategy as an equilibrium point. The procedure is equivalent to solving the maximin optimization problem with respect to the payoff $R(\mathbf{x}, \mathbf{y})$. In a similar manner, we can find the rational behavior of Customs while revising the estimation on the mixed strategy of the smuggler stage-by-stage and then finally derive an optimal smuggler's strategy, which is the same as an optimal solution of the minimax optimization problem. Anyway, the readers could refer to Reference [34] for more details.

A Model with Asymmetric Information

Let us discuss the second model of the inspection game, where information acquisition is asymmetric between players; Player B can

obtain some information but Player A cannot. In such a situation, Player A has to make a decision based on his belief on the characteristics of his opponent, the present state of the game, and others. In the model with incomplete information, the payoff of the game is expressed in different ways, relying on individual belief of each player. Player B can definitely recognize his reward or the payoff based on his correct information, but Player A would have some uncertainty in his payoff even though the payoff has the same meaning for both players. In many countries, Customs would be a public organization but the smuggler could be a secret society. Therefore, the behavior of Customs is comparatively open to outside but the smuggler's information is kept in secret. For the game with incomplete information, game theory presents us the concept of Bayesian–Nash equilibrium, by which we can understand the rationality on the player's behavior, taking account of the belief. Here, we are going to discuss the way to handle the inspection game with incomplete information or asymmetric information, in accordance with Reference [36]. The Bayesian–Nash equilibrium is the extended concept of Nash equilibrium, in which the entire combination of players' strategies and their beliefs has to be consistent with each other.

To deal with the incomplete information, we change Assumption A7 in Section 2 to the following.

- I1. At the beginning of a stage, the smuggler knows the strategy taken by Customs at the previous stage but the smuggler's past strategy is in secret to Customs. Both players recognize the occurrence of capture of the smuggler. The initial state of the game, (N, K, L) , is common knowledge for both players.

We can denote an exact state of the game by (n, k, l) , where Customs holds k chances to patrol and the smuggler has l chances to smuggle at Stage n . At the beginning of the stage n , the smuggler correctly recognizes the state (n, k, l) . But Customs knows only (n, k) and anticipates the number l by his belief on it. Let us denote his belief

by a probability distribution $q_n = \{q_n(l), l = \underline{l}_n, \underline{l}_n + 1, \dots, \bar{l}_n\}$, where $q_n(l)$ is the probability that the smuggler has l chances of smuggling left and satisfies conditions $\sum_l q_n(l) = 1$ and $q_n(l) \geq 0$. The lower bound $\underline{l}_n$ of l is estimated by everyday smuggling, and the upper bound $\bar{l}_n$ is calculated by no smuggling, as follows: $\underline{l}_n = \max\{L - N + n, 0\}$, $\bar{l}_n = \min\{L, n\}$. We refer to the smuggler with l chances of smuggling as the l -type smuggler. Customs has the perfect belief of

$$q_N(L) = 1, \quad q_N(l) = 0 (l \neq L) \quad (4)$$

only at the first stage N .

Before discussing the difference between payoffs of two players, we are going to define strategies of players. For Customs knowing the state (n, k) , we denote the probability of taking P or NP by x_n or $1 - x_n$, respectively. For the l -type smuggler recognizing the state (n, k, l) , we use $y_n(l)$ or $1 - y_n(l)$ as the probability of taking smuggling (S) or not-smuggling (NS). We illustrate a stage game in State (n, k, l) by Table 1, similarly to a matrix game.

Table 1. A Table of Payoffs in State (n, k, l)

Belief	$q_n(\underline{l}_n)$	$q_n(l)$	$q_n(\bar{l}_n)$
		...	$y_n(l), 1 - y_n(l)$
	C/S	S, NS	...
		S, NS	S, NS
x_n	P	...	(1), (2)
$1 - x_n$	NP	...	(3), (4)

where (1) through (4) have to be replaced with

1. $R_l(P, S) \equiv \alpha p - q + (1 - p)v(n - 1, k - 1, l - 1; \Gamma_P(q_n))$,
2. $R_l(P, NS) \equiv v(n - 1, k - 1, l; \Gamma_P(q_n))$,
3. $R_l(NP, S) \equiv -1 + v(n - 1, k, l - 1; \Gamma_N(q_n))$,
4. $R_l(NP, NS) \equiv v(n - 1, k, l; \Gamma_N(q_n))$.

$\Gamma_P(q_n)$ and $\Gamma_N(q_n)$ are the posterior beliefs revised from q_n at the beginning of the next stage $n - 1$, depending on Customs' present strategy P and NP , respectively,

and $v(n, k, l; q_n)$ is the expected payoff of the smuggler from the current state (n, k, l) to the end of the game. Please note that x_n or $y_n(l)$ ought to be zero in the case of $k = 0$ or $l = 0$, respectively, because Customs or the smuggler has only one choice of NP or NS in such cases.

Now let us derive the expected payoffs of two players and see a difference between them. Customs with belief q_n would expect the following payoff $P(x_n, y_n)$ and want to maximize the payoff by changing his strategy x_n .

$$\begin{aligned} P(x_n, y_n) = & \sum_{l=\underline{l}_n, l \neq 0}^{\bar{l}_n} q_n(l) [x_n \{y_n(l) R_l(P, S) \\ & + (1 - y_n(l)) R_l(P, NS)\} \\ & + (1 - x_n) \{y_n(l) R_l(NP, S) \\ & + (1 - y_n(l)) R_l(NP, NS)\}]. \end{aligned} \quad (5)$$

On the other hand, the type- l ($l \in [\underline{l}_n, \bar{l}_n]$, $l \neq 0$) smuggler correctly knows the present state (n, k, l) and would desire to minimize the following expected payoff by changing his strategy $y_n(l)$.

$$\begin{aligned} V_l(x_n, y_n(l)) = & x_n \{y_n(l) R_l(P, S) \\ & + (1 - y_n(l)) R_l(P, NS)\} \\ & + (1 - x_n) \{y_n(l) R_l(NP, S) \\ & + (1 - y_n(l)) R_l(NP, NS)\}. \end{aligned} \quad (6)$$

We notice that the asymmetry of information acquisition between two players bears some difference between expressions (5) and (6), but we also notice that $V_l(x_n, y_n(l))$ is contained in $P(x_n, y_n)$ as a part. Therefore, we can regard the stage game in State (n, k, l) as a TPZS game with the expected payoff $P(x_n, y_n)$ between Customs and all types of smugglers.

We derive a Bayesian-Nash equilibrium at each stage n by finding the optimal strategy x_n^* of maximizing $P(x_n, y_n)$, the optimal strategy $y_n^*(l)$ of minimizing $V_l(x_n, y_n(l))$ for all l s, and the rational belief $\{q_n^*(l)\}$ of being revised from $\{q_{n+1}(l)\}$ by $y_n^*(l)$ and having a consistency with its initial condition 4. A combination of optimal strategies $x_n^*, n \in N$, $\{y_n^*(l), l \in [\underline{l}_n, \bar{l}_n], n \in N\}$ and rational belief

$\{q_n^*(l), l \in [l_n, \bar{l}_n], n \in \mathbf{N}\}$ through all stages $\mathbf{N}$ is the *Bayesian-Nash equilibrium*. The derivation of the Bayesian-Nash equilibrium is usually tough in reality, and its numerical derivation requires a smart algorithm (refer to Hohzaki [36,37] for more details).

In Section 2, we described the multistage inspection game, in which both players can acquire their opponents' information. In this section, we have looked through the models with no-information and asymmetric information. By comparing with the values of the games, we can evaluate the value of information.

INTERDICTION GAMES AND AMBUSH GAMES

As mentioned in "Introduction", the study on the interdiction game was accelerated since the United States was confronted with the smuggling problem of drugs from Latin America in the 1980s. In a network theoretical context, Ford and Fulkerson [38] found the minimum cost interdiction against all paths from a start node s to a destination node t by the well-known max-flow min-cut theorem, although their problem is not a game. If we associate an arc (i, j) with a cost r_{ij} to break it, the minimum total cost to disrupt all paths from s to t is given by a minimum $s-t$ cut after corresponding r_{ij} to the capacity of arc (i, j) . For the interdiction game, Wollmer [39] discussed a game between an interdictor and an evader in a military context.

Let us see the basic model of Washburn and Wood [19]. An evader attempts to traverse a path from node s to node e through a network, which consists of a set of nodes $\mathbf{N}$ and a set of arcs $\mathbf{A}$, without being detected by an interdictor. The interdictor selects an arc k and sets up an inspection site. If the evader traverses the arc k , he is detected with probability p_k . Otherwise, he goes undetected. The interdiction game is the TPZS game with the payoff of the interdiction probability, in which an evader's strategy is the selection of a path and an interdictor's strategy is the selection of an arc for inspection. Let

us denote an evader's mixed strategy by $\hat{\mathbf{y}} = \{\hat{y}_l, l \in L\}$, where L is a set of all paths from s to e and $\hat{y}_l$ is the probability of taking path l , and an interdictor's mixed strategy by $\mathbf{x} = \{x_k, k \in \mathbf{A}\}$, where x_k is the probability to inspect the arc k . For an interdictor's mixed strategy $\mathbf{x}$ and an evader's mixed strategy $\hat{\mathbf{y}}$, the expected payoff is given by $V(\mathbf{x}, \hat{\mathbf{y}}) = \sum_{k \in \mathbf{A}} \sum_{l \in L} x_k p_k d_{kl} \hat{y}_l$, where d_{kl} is 1 if path l includes arc k and 0 otherwise, referred to as the *arc-path incident matrix*. The minimax optimization of this basic problem is easily formulated as follows: $\min_v$ s.t. $\sum_{l \in L} p_k d_{kl} \hat{y}_l \leq v (k \in \mathbf{A})$, $\sum_{l \in L} \hat{y}_l = 1$, $\hat{y}_l \geq 0 (l \in L)$. The authors showed that an optimal strategy x_k^* of the interdictor is inversely proportional to p_k if k belongs to a minimum cut on the network with capacity p_k and is zero otherwise.

The authors also extended the basic problem to some advanced versions with multiple sources and sinks, multiple evaders, or multiple interdictors from the point of view of mathematical programming. There are also some researches to deal with interdiction games for analysis on communication networks. Kodialam and Lakshman [40] developed a sampling strategy of network packets to effectively detect network intrusions within a given sampling budget. The interdiction game is sometimes called the *infiltration game* from the opposite coloration [41,42].

The ambush game has almost the same situation as the interdiction game. If we regard the research on the passage control of a submarine by anti-submarine warfare (ASW) airplanes in straits as an ambush game, we can say that Morse and Kimball discussed the first example of the ambush game in *Methods of Operations Research* [43]. While the interdiction game is focused on networks in many models, the ambush game is usually considered in general regions such as a rectangular lattice or a continuous rectangle.

Ruckle [27,44] introduced an original ambush game, in which Blue wishes to move across a rectangular lattice to avoid being ambushed by Red, who wants to place obstacles in the Blue's path. Let us consider the lattice having m rows and n

columns. Blue sets up a function f from domain $\{1, 2, \dots, n\}$ into range $\{1, 2, \dots, m\}$ as his path, and Red chooses a set of some points A from mn points in the lattice area under some constraints. For f and A , the payoff of the game $R(f, A)$ is defined to be 1 if $(i, f(i)) \notin A$ and 0 if $(i, f(i)) \in A$. Ruckle found optimal solutions in three cases. Let us see his results in two cases of them. In Case 1, Red cannot choose more than $k (< m)$ points from the lattice. An optimal mixed strategy of Blue is to pick up every integer j from $\{1, 2, \dots, m\}$ as $f(i) = j$ with probability $1/m$. An optimal mixed strategy of Red is to choose one from all combinations of choosing k from m points in a column with equal probability $1/\binom{m}{k}$. These strategies bring the value of the game $1 - k/m$. In Case 2, Red has the constraints that the number of points to pick up in a column is $c (< m)$ at most as well as the total number of points up to k . In this case, an optimal strategy of Red consists of first choosing $p + 1$ columns at random and then randomly picking up c points in p columns out of the $p + 1$ columns and q points in the rest one column, where p and q are the integers satisfying $k = pc + q (0 \leq q < c)$. In such a manner, each combination is taken with equal probability $1/\binom{m}{c}^p \binom{m}{q}$. An optimal strategy of Blue is to choose a row j and keep $f(i) = j$ for every column i with probability $1/m$ or to pick a point in every column at completely random, that is, to take one out of all combinations of $f(i) = j$ for $i \in \{1, \dots, n\}$ and $j \in \{1, \dots, m\}$ with probability $1/m^n$. The value of the game becomes $(1 - c/m)^p (1 - q/m)$. The similar game is modeled on a two-dimensional continuous space.

Some researchers considered other situations of ambushing by Red. Red has two barriers of lengths a and b , which can be laid anywhere in an interval, and can detect the Blue's crossing at a point that intersects these barriers. The problem is referred to as *Ruckle problem*. Garnaev [45] considered a discrete version of the problem on a discrete interval $[1, n]$ of integers. The ambush game has been now gotten up-to-date such that a variety of barriers are available to Red, for example.

In order to use an optimization solver, it is necessary to communicate a model instance to the solver. Early users of optimization solvers often created a specific model instance from input data by writing a *matrix generator*. Mixed-integer linear programming (MILP) solvers such as IBM's MPSX/370 package and LINDO provided an application program interface that allowed a user to write a matrix generator in a procedural programming language such as PL/I or Fortran. The matrix generator was then linked to the solver library to produce an executable program that solved the specific instance. The term *matrix generator* arose because, initially, the most widely used optimization solvers were for MILP, and specifying the constraint matrix and objective function vector was sufficient to describe a model instance [along with a characterization of variable types and bounds and constraint right-hand sides (RHS)].

Matrix generators were tightly coupled with the solver because the model instance was communicated directly in-memory to the solver. However, modelers still needed to store the model instance in a persistent state for archival, communication, and debugging purposes. The classic MPS format was the first widely adopted instance format. It was

developed by William Orchard-Hays [1,2], it is based on an earlier format developed for the IBM 704 [3]. Even today, most LP (linear programming) and MILP solvers read and write files in MPS format.

The development of *algebraic modeling languages* represented a major breakthrough for the field of operations research because they greatly reduced the effort required to produce an optimization model instance. Modeling languages such as GAMS [4] and AMPL [5] that communicate with solvers by writing an instance to a file, have resulted in additional instance formats. Indeed, both GAMS and AMPL have their own instance representation formats. There now exists a plethora of proposed instance formats, depending on the optimization type. In Table 1 we list some key optimization types and corresponding formats. This table is illustrative, but by no means complete.

It is crucial to understand the difference between an algebraic model and a specific instance of that model. The description of a specific optimization instance is very different from the description of a generic algebraic model. An algebraic model description is *symbolic, general, concise, and understandable* [6]. An algebraic model contains declarations of high-level algebraic components such as sets, parameters, variables, objectives, and constraints. It is designed to be easily written and read by humans and often does not contain specific parameter values. By contrast, a model instance is designed to be read directly by a solver and all parameter values must be specified. An algebraic modeling language takes a model and compiles it into an instance using a specific data set. An LP model instance is illustrated in Fig. 1. (The details of this representation are discussed in the section titled "Optimization Instance Format.") An appropriate analogy from object-oriented programming is that the algebraic model corresponds to a class and the model instance corresponds to an *instantiated* object in that class.

Table 1. Optimization Classes and Proposed Formats

Optimization Type	Instance Format
Mixed-integer linear program	MPS, lpsolve-lp, CPLEX-lp, AMPL nl, OSiL, OptML, GAMS dat
Nonlinear	xMPS, MOI, SIF, OSiL, AMPL nl, GAMS dat, LINDO MPI
Stochastic linear programming	SMPS, OSiL
Quadratic	MPS, OSiL
Semidefinite and second-order cone	sparse SDPA, SDPLR, OSiL
Linear network optimization	NETGEN, NETFLO, DIMACS, RELAX4
Traveling salesman problem	tsp

In this article we review existing instance formats for optimization problems, solver options, and solver results. We describe the research issues involved in designing instance formats. We do not address algebraic models.

In the next section we discuss key issues that must be considered when designing

an instance format. In the section titled “Optimization Instance Format” we describe formats for representing optimization problem instances. In addition to optimization instances, it is necessary to have formats for solver options (section titled “Solver Option Instance Format”) and results (section titled “Solver Result Instance Format”). There are obviously numerous types of optimization models. Extensions to some of the more recently studied optimization areas are the topic of the final section.

KEY DESIGN ISSUES

There are several key design issues when designing an instance representation. First is the decision of which instance to represent. Is the proposed format only for the problem instance, or does it include instances of solver options, solver results, or instance modifications? This is discussed more thoroughly in the following section. Then there is the key issue of how to format or represent problem instance information. This is discussed in the section on key issue 2. The next issue is how comprehensive and extensible the representation should be. This is discussed in the

section on design of the format. Finally, there is the issue of how the instance representations map to in-memory objects on the solver side. This is discussed in the section on key issue 4.

Key Issue 1: Separation of Functionality

In a modeling language-solver infrastructure, an instance passed to the solver must contain information on the problem to be optimized and may specify solver options. Likewise, a result is returned from the solver. There are actually four distinct instance formats that can be specified.

1. Optimization *problem* instance format—this is discussed briefly in the section on key issue 2 and in greater detail in the section titled “Optimization Instance Format”.
2. Solver *option* instance format—it is often necessary to pass options to a solver. This is a challenge given the wide variety of solvers and a complete lack of a standard for option formats. See the corresponding section for a proposed standard.
3. Solver *result* instance format—after a problem is solved (or terminated) results must be passed back from the solver to the client. See the corresponding section for more discussion on result instance formats.
4. Instance *modification* format—there are many solution procedures such as column generation and cutting plane algorithms that require modifying the original problem instance. Aside from the possibility of specifying multiple objectives and RHS in MPS, and switching between them, there is no standard instance modification format that the authors are aware of. This is a good topic for further research.

Key Issue 2: Problem Instance Format

A typical optimization problem instance might include millions of nonzero coefficients in linear terms and hundreds, if not thousands, of nonlinear terms. A

central problem in representing instances is managing these entries and ensuring that they are handled correctly and efficiently. There are three basic styles or formats that have been used to represent a model instance.

Natural Algebraic Format. Consider the simple constraint $.5x_0 + .8333x_1 \leq 600$. One way to represent this constraint instance is in its natural algebraic format. For example, in the LINDO solver [7], this constraint is expressed as

```
R0000001) +0.5 x0 + 0.8333 x1 < +600.
```

Other solvers have similar algebraic formats, for example CPLEX-lp file format [8], lpsolve lp-format, and Xpress lp-format [9,10]. Three important features of this format are that (i) it is easily read by a human and convenient for debugging purposes; (ii) it naturally extends to the nonlinear case; and (iii) it can exploit supersparsity [11]. With regard to the third point, we could rewrite

```
3.141592654*x1 +3.141592654*x2
+3.141592654*x3 + ...
```

as

```
3.141592654*( x1 + x2 + x3 + ... )
```

Modeling Language Specific Format. Modeling languages take an algebraic model and compile it with the data to produce a model instance. In the case of modeling languages such as AMPL [5] and GAMS [4], the model instance is temporarily written to a file which is then read by the solver. In order to make this process efficient, modeling languages use a parsimonious representation and do not store variable names. For example, the body of the constraint $.5x_0 + .8333x_1 \leq 600$ has the following representation in the AMPL nl format [12]:

```
J1 2
0 0.5
1 0.8333.
```

For more on how to interpret these lines and on representing the RHS, see the section titled “Optimization Instance Format”. Parsimony is important since problem instances are often exchanged over a network.

Markup Language Format. Yet another option for model instance representation is to use a markup language such as extensible markup language (XML). Two proposed XML-based instance formats are OSiL [13] and OptML [14]. An instance representation in OSiL is provided in the section titled “Optimization Instance Format.” Although apparently verbose, there are good reasons to use XML for an instance format. First, an instance represented in XML has both markup and data which allow for easy parsing and compression. Second, an instance in XML format can be validated against a schema which is important for error checking. The W3C XML schema standard permits developers of XML schemas to define their own data types called `complexType`s. The `complexType` is used to specify the elements and attributes that are allowed to appear in a valid XML instance file such as the one shown later in Fig. 3. The use of XML also facilitates the design of the corresponding in-memory instance (see the section on key issue 4). Third, XML is becoming the *lingua franca* of data storage in industry and using this format makes optimization modeling conform with modern information technology infrastructures (a more thorough discussion can be found in Ref. 15).

Key Issue 3: Design of Format: Level of Detail and Flexibility

An optimization problem instance is a well-defined entity. A certain amount of detail is required and it is not possible to be flexible in deciding whether or not certain problem components should be present. For example, we cannot have a linear program without constraints or variables. However, there is more flexibility in reporting the solution of an optimization problem. For example, in a LP solution, we may or may not have reduced costs or RHS sensitivity information. In general, different optimization solvers may present their results in different formats,

and some may include more detail than others. The level of solution detail is up to the solver developer and would be difficult to standardize. Similar logic applies to solver options. Thus, when representing a problem instance, it is necessary to express the instance in a very rigorous fashion. However, when designing option or result instances, flexibility may be more desirable. We elaborate on this issue in the sections titled “Solver Option Instance Format” and “Solver Result Instance Format.”

Key Issue 4: Design of an In-Memory Instance Object

In various situations, for example when using a modeling language such as GAMS or AMPL, the problem instance may be serialized (e.g., written to a file) and then deserialized (e.g., read back into memory) by the solver. The way in which a problem instance is represented in memory may look very different from the format that persists in a string or file. There is no “standard way” to represent, for example, an instance in the MPS format as an in-memory object. The optimization services (OS) framework is the first to specify a set of mapping or binding rules on how to transform the persistent instance format into in-memory objects. The OS format (OSiL) for representing an instance is based on a W3C XML schema. The use of a schema to specify the XML instance format is key to providing a binding between the format and the `OSInstance` class which is the in-memory representation of the optimization problem instance. For example, each XML schema `complexType` corresponds to a class in `OSInstance`. For more details on this binding see Ref. 13.

OPTIMIZATION INSTANCE FORMAT

Instance formats are used to store problem instances in a file or string before sending them to the solver. These can be created by hand, or be output from a matrix generator or an algebraic modeling language. Formats can be either text or binary.

An instance format must be able to represent all components of a problem instance.

Special purpose formats for narrow problem classes, such as traveling salesman problems, might have more restricted requirements and be more compact than formats for general problems but some problem components such as decision variables, objectives, and constraints are universal to all problem classes.

Information about the number of variables and constraints must be contained in the instance format, but there are at least two ways to accomplish this goal. For example, the AMPL nl format [12] has a header section that contains explicit information about the number of continuous, integer, and binary variables and breaks this down further into variables that appear in nonlinear expressions in the objective, constraints, both, or neither. The MPS format [16], on the other hand, contains the information implicitly and requires the reader to keep count of the variables as the instance is being processed. This is similar for constraints. Many instance formats (one notable exception being the MPS format) assume that the problem has a unique objective, so that there is no need to record the number of objectives. Obviously, formats designed to handle multiobjective problems must be able to express the number of objectives found in the problem instance.

Along with the number of decision variables, it is necessary to store information about them, such as upper and lower bounds. Finally, for report generation purposes and communication of the optimization result to the user, it is desirable that each variable have a unique identifier, which may or may not be communicated to the solver. For that reason, some instance formats refer to variables as well as constraints by number, while others, including the MPS format, refer to them by name. The latter allows more flexibility in the ordering of certain problem components but is more costly to parse.

The biggest challenge for a problem instance format is handling nonzero elements in the constraints. In problems of realistic size, it is essential to exploit sparsity in the linear, quadratic, and nonlinear components of the problem. Sparse representations of linear constraint matrices

can be achieved in several different ways. MPS records the matrix coefficients column by column as triples of (*column*, *row*, *value*), where *column* and *row* are names instead of numbers. This storage scheme results in the variable name being repeated for each row in which the variable has a nonzero value. AMPL nl format stores the constraint matrix by rows with markers separating one row from another, and with column number and coefficient value for every nonzero value in the row. OSiL uses the sparse matrix format [17], which is a combination of three arrays giving the column starts, row indices, and coefficient values when storing the constraint matrix by columns. OSiL can also store the constraint matrix by row using row starts, column indices, and coefficient values. Row and column representations work equally well for representing a constraint matrix. However, as we see at the end of this section, row-wise storage is more general and natural for nonlinear programs.

As an illustration of the above ideas, we offer the following small LP problem [18]:

$$\begin{aligned} \max \quad & 10x_0 + 9x_1 \\ \text{s.t.} \quad & 0.7x_0 + 1.0x_1 \leq 630, \\ & 0.5x_0 + 0.8333x_1 \leq 600, \\ & 1.0x_0 + 0.6667x_1 \leq 708, \\ & 0.1x_0 + 0.25x_1 \leq 135. \end{aligned} \tag{1}$$

Figure 1 is a representation of instance (1) in MPS format. Lines 3–7 set up the objective and constraint rows, the number being determined implicitly. Lines 9–11 give the objective and constraint coefficients associated with the first column, x_0 ; lines 12–14 give the coefficients for the second column, x_1 . Lines 16–19 specify the RHS values associated with the four constraints.

The AMPL nl format can be stored in either binary or text format; we give the text form for instance (1) in Fig. 2. The annotated section of the problem (lines 1–10) is used to set up the problem dimension; the next ten lines are used to show any nonlinear expressions (of which there are none, as indicated by the special code `n0` in lines 12,

Figure 3. A sample OSiL file.

for representing linear, integer, quadratic, and nonlinear problem instances as well as a large number of special features, such as multiobjectives, stochastic programs, cone programs, special ordered sets (SOS), and others. The OSiL format is largely self-documenting, so we only highlight a few main points. Header information is given in lines 3 to 5. The actual optimization data start in line 6. Separate sections give

information about variables (lines 7–10: bounds, variable type, and an optional name), objective function (lines 12–16: direction of optimization and objective coefficients) and constraints (lines 19–22: RHS values).

In OSiL XML markup the constraint matrix is represented in sparse matrix format [17], either by row or by column. In this example we are storing by column (often called the column major). In column-major

storage, the k^{th} `<start>` element in line 26 points to the start of the column k row indexes (contained in lines 29–32) and the column k coefficient values (contained in lines 35–38). The last `<start>` element (in this case 8) value is the number of nonzero elements.

Due to the availability of fast LP codes, linear models were initially of primary interest. However, as progress is made with nonlinear solution algorithms, there is increased interest in formats for nonlinear instances. For example, there are a number of solvers that now support objectives and constraints with quadratic terms and second-order cone constraints. There are even extensions of the MPS format to allow for quadratic terms (QMATRIX) and second-order cone constraints (CSECTION). See for example, Ref. 19, for an illustration of both the QMATRIX and CSECTION MPS formats. Rather than detail these specific extensions we address representation of general nonlinear optimization problems.

There are several ways in which general nonlinear expressions can be captured in an instance format. We illustrate with a modification of the Rosenbrock function [20]. The model is as follows:

$$\begin{aligned}
 \min \quad & (1 - x_0)^2 + 100 * (x_1 - x_0^2)^2 + 9 * x_1 \\
 \text{s.t.} \quad & x_0 + 10.5 * x_0^2 + 11.7 * x_1^2 \\
 & + 3 * x_0 * x_1 \leq 25, \\
 & \ln(2 * x_0 * x_1) + 7.5 * x_0 \\
 & + 5.25 * x_1 \geq 10.
 \end{aligned} \tag{2}$$

In instance (2), the terms $100 * (x_1 - x_0^2)^2$ and $\ln(2 * x_0 * x_1)$ are not quadratic and must use a more general representation. We illustrate approaches to modeling general nonlinear terms using the $\ln(2 * x_0 * x_1)$ term. The standard algebraic format $\ln(2 * x_0 * x_1)$ is *infix notation* [21] and is ambiguous with regard to the order of operations. The ambiguity is resolved by using parentheses (or by convention with regard to operator precedence and left or right associativity), where, for example, $\ln((2 * x_0) * x_1)$ specifies an order of operations. Due to the

infix ambiguity, most instance formats store each nonlinear term as a *prefix* or *postfix* sequence of operands and operators. The list of operators and operands is also called an *instruction list*. The prefix and postfix sequences for $\ln((2 * x_0) * x_1)$ are

```
ln * * 2 x0 x1
```

and

```
x1 2 x0 * * ln,
```

respectively. A prefix or postfix instruction list is trivial to evaluate using a stack data structure and is also convenient for algorithmic or automatic differentiation. The postfix or prefix instruction list is a key part of several instance formats. For example, the AMPL nl format uses prefix combined with numerical codes for the operators `ln` and `*` and writes

```
o43
o2
o2
n2
v0
v1,
```

where `o43` is the code for the logarithm operator, `o2` is the code for the multiplication operator, and `n` and `v` denote references to numbers and variables, respectively.

The OSiL instance format also corresponds to a prefix instruction list. The term $\ln((2 * x_0) * x_1)$ in OSiL is

```
<nl idx="1">
  <ln>
    <times>
      <times>
        <number type="real" value="2.0"/>
        <variable coef="1.0" idx="0"/>
      </times>
      <variable coef="1.0" idx="1"/>
    </times>
  </ln>
</nl>.
```

The sequence of open tags is

```
<ln><times><times><number><variable><variable>
```

and corresponds directly to the prefix instruction list.

A nonlinear extension of MPS based on postfix is described by Halldórsson *et al.* [22]. It puts the postfix instruction list into the MPS record structure. For example, $\ln((2 * x_0) * x_1)$ is written as

```
NONLINEAR
CON1 V1 mult 2 X0
CON1 V2 mult V1 X1
CON1 RES ln V2.
```

Lines 2 and 3 compute the product $2x_0x_1$ and store it into the intermediate object V2; the last line computes the natural logarithm of V2 and stores into the reserved object RES, which is used to designate the final result of the computation, which gets added to the linear and quadratic terms for constraint CON1.

A completely different format, SIF (standard input format), was developed by Conn *et al.* [23,24]. A SIF file consists of two pieces, a declarative portion in which a number of declarations of auxiliary quantities are interspersed with declarations of variables, objectives, and constraints, and a procedural portion where the nonlinear functions are defined in terms of the original variables and coefficients as well as the auxiliary quantities previously defined. SIF is a very complex and far-reaching proposal that did not achieve universal acceptance.

Formats for specialized problems can occasionally streamline the information needs and reduce, often greatly, the size of the resulting instance file. For instance, a stochastic programming problem may need to record values for problem coefficients that take different values in a number of different scenarios, along with a number of deterministic coefficients that do not change from one scenario to the next. If the random variables are time-staged, this can lead to a geometric explosion of the event tree. The SMPS format for stochastic programs reduces redundancy by storing only the stochastic components explicitly. When the random variables are independent from one stage to the next, the SMPS format can store the event tree in linear space. See Ref. 25 for more details. Similar features are available in OSiL [26]. Compact specialized instance formats exist for other problem classes,

such as semidefinite cone programming, network problems, and traveling salesman problems.

SOLVER OPTION INSTANCE FORMAT

Solver options are an integral part of the solution process and are usually tied to the problem instance. Traditionally, there have not been any standards for the communication of options since each solver tended to have its own application programming interface (API) with which the user communicates either through files, command line options or interactive keyboard inputs.

Standardizing the input format for solver options is hard since the options tend to be very specific to the solver and algorithm. In designing a common format it is useful to break down the process into syntax (how to represent options) and semantics (how to interpret their meanings). While the former is relatively easy to standardize, the latter is nearly impossible, even though a number of common options may be identified that are implemented in the majority of solvers. Standard option formats therefore, need to be both rigid in format and flexible in content, and must be extensible to leave room for future solver development.

The development of option formats is driven by other considerations as well. Since solver options form only part of the input sent to a solver, it is desirable to have some way to ensure that the options are linked to the correct problem instance. This is necessary particularly where the options provide values for the elements of an instance component, such as initial variable values. Some solvers such as LINDO allow solver options to have different scopes, applying either to one particular problem only, or to the entire solver environment. This is useful because it allows the user to set an output level once for a series of problems, instead of having to repeat the information for each separate problem.

Solvers are not the only component of a mathematical programming system; options could be sent to an optimization analyzer or simulation tool. If a large environment has

such diverse tools, it seems advantageous to design option formats that can be shared among all components. In order to establish the correct match of option file and analysis tool, the intended target must be recorded in the option file. Additionally, especially in a commercial environment, basic security features such as license information, username, and password may be needed in the options file. Finally, especially in a distributed environment, additional facilities are often needed to monitor the progress of the solution process on the remote computer, to verify capabilities of the computer system on which the solver is to be run, and perhaps to perform ancillary file operations before and after the solution.
